MOLECULAR CELL BIOLOGY

ABOUT THE AUTHORS

HARVEY LODISH is Professor of Biology and Professor of Bioengineering at the Massachusetts Institute of Technology and a Founding Member of the Whitehead Institute for Biomedical Research. Dr. Lodish is also a member of the National Academy of Sciences and the American Academy of Arts and Sciences and was President (2004) of the American Society for Cell Biology. He is well known for his work on cell-membrane physiology, particularly the biosynthesis of many cell-surface proteins, and on the cloning and functional analysis of several cell-surface receptor proteins, such as the erythropoietin and TGF- β receptors. His laboratory also studies hematopoietic stem cells and has identified novel proteins that support their proliferation. Dr. Lodish teaches undergraduate and graduate courses in cell biology and biotechnology. **Photo credit:** John Soares/Whitehead Institute.

ARNOLD BERK holds the UCLA Presidential Chair in Molecular Cell Biology in the Department of Microbiology, Immunology, and Molecular Genetics and is a member of the Molecular Biology Institute at the University of California, Los Angeles. Dr. Berk is also a fellow of the American Academy of Arts and Sciences. He is one of the original discoverers of RNA splicing and of mechanisms for gene control in viruses. His laboratory studies the molecular interactions that regulate transcription initiation in mammalian cells, focusing in particular on adenovirus regulatory proteins. He teaches an advanced undergraduate course in cell biology of the nucleus and a graduate course in biochemistry.

CHRIS A. KAISER is Professor and Head of the Department of Biology at the Massachusetts Institute of Technology. His laboratory uses genetic and cell biological methods to understand the basic processes of how newly synthesized membrane and secretory proteins are folded and stored in the compartments of the secretory pathway. Dr. Kaiser is recognized as a top undergraduate educator at MIT, where he has taught genetics to undergraduates for many years.

MONTY KRIEGER is the Whitehead Professor in the Department of Biology at the Massachusetts Institute of Technology and a Senior Associate Member of the Broad Institute of MIT and Harvard. Dr. Krieger is also a member of the National Academy of Sciences. For his innovative teaching of undergraduate biology and human physiology as well as graduate cell-biology courses, he has received numerous awards. His laboratory has made contributions to our understanding of membrane trafficking through the Golgi apparatus and has cloned and characterized receptor proteins important for pathogen recognition and the movement of cholesterol into and out of cells, including the HDL receptor.

ANTHONY BRETSCHER is Professor of Cell Biology at Cornell University and a member of the Weill Institute for Cell and Molecular Biology. His laboratory is well known for identifying and characterizing new components of the actin cytoskeleton and elucidating the biological functions of those components in relation to cell polarity and membrane traffic. For this work, his laboratory exploits biochemical, genetic, and cell biological approaches in two model systems, vertebrate epithelial cells and the budding yeast. Dr. Bretscher teaches cell biology to undergraduates at Cornell University.

HIDDE PLOEGH is Professor of Biology at the Massachusetts Institute of Technology and a member of the Whitehead Institute for Biomedical Research. One of the world's leading researchers in immune system behavior, Dr. Ploegh studies the various tactics that viruses employ to evade our immune responses and the ways our immune system distinguishes friend from foe. Dr. Ploegh teaches immunology to undergraduate students at Harvard University and MIT.

ANGELIKA AMON is Professor of Biology at the Massachusetts Institute of Technology, a member of the Koch Institute for Integrative Cancer Research, and Investigator at the Howard Hughes Medical Institute. She is also a member of the National Academy of Sciences. Her laboratory studies the molecular mechanisms that govern chromosome segregation during mitosis and meiosis and the consequences—aneuploidy—when these mechanisms fail during normal cell proliferation and cancer development. Dr. Amon teaches undergraduate and graduate courses in cell biology and genetics.

**To our students and to our teachers,
from whom we continue to learn, and to our families,
for their support, encouragement, and love**

PREFACE

In writing the seventh edition of *Molecular Cell Biology* we have incorporated many of the spectacular advances made over the past four years in biomedical science, driven in part by new experimental technologies that have revolutionized many fields. Fast techniques for sequencing DNA and RNA, for example, have uncovered many novel noncoding RNAs that regulate gene expression and identified hundreds of human genes that affect diseases such as diabetes, osteoporosis, and cancer. Genomics has also led to many novel insights into the evolution of life forms and the functions of individual members of multiprotein families. Exploring the most current developments in the field is always a priority in writing a new edition, but it is also important to us to communicate the basics of cell biology clearly. To this end, in addition to introducing new discoveries and technologies, we have streamlined and reorganized several chapters to clarify processes and concepts for students.

New Co-Author, Angelika Amon

The new edition of *MCB* introduces a new member to our author team, respected researcher and teacher Angelika Amon of the Massachusetts Institute of Technology. Her laboratory uses the budding yeast *S. cerevisiae* and mouse and cell culture models to gain a detailed molecular understanding of the regulatory circuits that control chromosome segregation and the effects of aneuploidy on cell physiology. Dr. Amon also teaches undergraduate and graduate courses in Cell Biology and Genetics.

Revised, Cutting Edge Content

The seventh edition of *Molecular Cell Biology* includes new and improved chapters:

- “Molecules, Cells and Evolution” (Chapter 1) now frames cell biology in the light of evolution: this perspective explains why scientists pick particular unicellular and multicellular “model” organisms to study specific genes and proteins that are important for cellular function.
- “Culturing, Visualizing, and Perturbing Cells” (Chapter 9) has been rewritten to include cutting edge methods including FRAP, FRET, siRNA, and chemical biology, making it a state-of-the-art methods chapter.
- “Signal Transduction and G Protein-Coupled Receptors” and “Signaling Pathways that Control Gene Expression” (Chapters 15 and 16) have been reorganized and illustrated

with simplified overview figures, to help students navigate the complexity of signaling pathways.

- “The Eukaryotic Cell Cycle” (Chapter 19) now begins with the concepts of “START” (a cell’s commitment to entering the cell cycle starting with DNA synthesis) and then progresses through the cycle stages. The chapter focuses on yeast and mammals and uses general names for cell cycle components when possible to improve student understanding.
- “Stem Cells, Cell Asymmetry, and Cell Death” (Chapter 21) now incorporates developmental topics, including new coverage of induced pluripotent stem (iPS) cells.

FIGURE 9-22 In this mouse fibroblast, FRET has been used to reveal that the interaction between an active regulatory protein (Rac) and its binding partner is localized to the front of the migrating cell.

Increased Clarity, Improved Pedagogy

As experienced teachers of both undergraduate and graduate students, we are always striving to improve student understanding. In this seventh edition, perennially confusing topics, such as cellular energetics, cell signaling, and immunology, have been streamlined and revised to improve student understanding. Each figure was reconsidered and, if possible, simplified to highlight key lessons. Heavily revised end-of-chapter materials include 30% new questions, including additional Analyze the Data problems to give students further practice at interpreting experimental evidence. The result is a balance of state-of-the-art currency and experimental focus with attention to clarity, organization, and pedagogy.

FIGURE 19-25 Stable and unstable chromosome attachments.

New Discoveries, New Methodologies

- Covalent regulation of protein activity by ubiquitination/deubiquitination (Ch. 3)
- Molecular chaperones including the Hsp90 family of proteins (Ch. 3)
- Mammalian protein synthesis and the roles of polymerases delta (lagging strand) and epsilon (leading strand) in eukaryotic DNA synthesis (Ch. 4)
- Non-radioactive probes (for in-situ hybridization, for example) (Ch. 5)
- Quantitative PCR (and RT-PCR) and high-throughput DNA sequencing (Ch. 5)
- DNA fingerprinting using microsatellites and PCR (Ch. 6)
- Personal genome sequencing and the 1000 Genome Project (Ch. 6)
- Epigenetic mechanisms of transcriptional regulation (Ch. 7)
- Transcriptional regulation by non-coding RNAs (e.g., Xist in X-chromosome inactivation, siRNA-directed heterochromatin formation in fission yeast and DNA methylation in plants) (Ch. 7)
- Fluorescent mRNA labeling to follow mRNA localization in live cells (Ch. 8)
- Structure and function of the nuclear pore complex (Chs. 8 and 13)
- Additional coverage of FRAP, FRET, and siRNA techniques (Ch. 9)
- Lipid droplets and their formation (Ch. 10)
- Assembly of the multiprotein T-cell receptor complex (Ch. 10)
- Structure of the Na^+/K^+ ATPase (Ch. 11)
- Structure and mechanism of the multidrug transporter ABCB1 (MDR1) (Ch. 11)
- Structure and function of the cystic fibrosis transmembrane regulator (CFTR) (Ch. 11)
- The role of an anion antiporter in bone resorption (Ch. 11)
- Structures of complex I and II as well as the mechanism of electron flow and proton pumping in the electron transport chain (Ch. 12)
- Generation and inactivation of toxic reactive oxygen species (ROS) (Ch. 12)
- The mechanism of proton flow through the half-channels of ATP Synthase (Ch. 12)
- Tail-anchored membrane proteins (Ch. 13)
- How modifications of N-linked oligosaccharides are used to monitor protein folding and quality control (Ch. 13)
- The mechanism of formation of multivesicular endosomes involving ubiquitination and ESCRT (Ch. 14)
- Advances in our understanding of autophagy as a mechanism for recycling organelles and proteins (Ch. 14)
- Affinity purification techniques for studying signal transduction proteins (Ch. 15)
- Structure of the β -adrenergic receptor in the inactive and active states and with its associated trimeric G protein, $G_{\alpha s}$ (Ch. 15)
- Activation of EGF receptor by EGF via the formation of an asymmetric kinase domain dimer (Ch. 16)
- Hedgehog signaling in vertebrates involving primary cilia (Ch. 16)
- NF- κ B signaling pathway and polyubiquitin scaffolds (Ch. 16)
- Integration of signals in fat cell differentiation via PPAR γ (Ch. 16)
- Mechanism of Arp2/3 nucleation of actin filaments (Ch. 17)
- The dynamics of microfilaments during endocytosis and the role of endocytic membrane recycling during cell migration (Ch. 17)
- Intraflagellar transport and the function of primary cilia (Ch. 18)
- Plant mitosis and cytokinesis (Ch. 18)
- +TIPs as regulators of microtubule (+) end function (Ch. 18)
- Proteins involved in mitotic spindle formation and kinetochore attachment to microtubules (Ch. 19)
- Elastic fibers that permit many tissues to undergo repeated stretching and recoiling (Ch. 20)

- Extracellular matrix remodelling and degradation by matrix metalloproteinases (Ch. 20)
- Stem cells in the intestinal epithelium (Ch. 21)
- Regulation of gene expression in embryonic stem (ES) cells (Ch. 21)
- Generation of induced pluripotent stem (iPS) cells (Ch. 21)
- Advances in our understanding of regulated cell death (Ch. 21)
- Structure of the nicotinic acetylcholine receptor (Ch. 22)
- Molecular model of the MEC-4 touch receptor complex in *C. elegans* (Ch. 22)
- Synapse formation in neuromuscular junctions (Ch. 22)
- Toll-like receptors (TLRs) and the inflammasome (Ch. 23)
- Epigenetics and cancer (Ch. 24)

Cells being born in the developing cerebellum.

Medical Relevance

Many advances in basic cellular and molecular biology have led to new treatments for cancer and other significant human diseases. These medical examples are woven throughout the chapters where appropriate to give students an appreciation for the clinical applications of the basic science they are

learning. Many of these applications hinge on a detailed understanding of multiprotein complexes in cells—complexes that catalyze cell movements; regulate DNA transcription, replication, and repair; coordinate metabolism; and connect cells to other cells and to proteins and carbohydrates in their extracellular environment.

The following is a list of new medical examples.

- Cholesterol transport and atherosclerosis as an illustration of the hydrophobic effect (Ch. 2)
- Use of genetically engineered corn with high lysine content to promote the growth of livestock as an illustration of importance of essential amino acids (Ch. 2)
- Poliovirus and HIV-1 as examples of viruses that infect only certain cell types due to tissue-specific cell surface receptors (Ch. 4)
- HPV vaccine and its ability to protect against common types of HPV, and the development of cervical cancer (Ch. 4)
- Huntington's disease as an example of a microsatellite expansion disease (Ch. 6)
- Potential treatment of cystic fibrosis using small molecules that would allow the mutant protein to traffic normally to the cell surface (Ch. 11)
- Role of genetic defects in *ClC-7*, a chloride ion channel, in the hereditary bone disease osteopetrosis (Ch. 11)
- Mitochondrial diseases such as Charcot-Marie-Tooth disease and Miller syndrome (Ch. 12)
- Use of ligand-binding domains of cell-surface receptors as therapeutic drugs, such as the extracellular domain of TNF α receptor to treat arthritis and other inflammatory conditions (Ch. 15)
- Role of Hedgehog (Hh) signaling in human cancers including medulloblastomas and rhabdomyosarcomas (Ch. 16)
- Role of B-Raf kinase in melanoma and use of selective inhibitors of B-Raf in cancer treatment (Ch. 16)
- Defects in a regulator of dynein as a cause of lissencephaly (Ch. 18)
- Elastic fiber protein fibrillin 1 and Marfan's Syndrome (Ch. 20)
- Use of iPS cells in uncovering the molecular basis of ALS (Ch. 21)
- Variations in human sense of smell (Ch. 22)
- Microarray analysis of breast cancer tumors as a way to distinguish gene expression patterns and individualize treatment (Ch. 24)

MEDIA AND SUPPLEMENTS

For Students

NEW **BioPortal for *Molecular Cell Biology*** A robust teaching and learning tool with all of the study and quizzing resources available through the Companion Web Site (listed below) as well as a fully-interactive eBook. BioPortal also includes **NEW LearningCurve**, a self-paced adaptive quizzing tool for students. With questions tailored to their target difficulty level and an engaging scoring system, LearningCurve encourages students to incorporate content from the text into their study routine and provides them with a study plan upon completion.

Companion Web Site www.whfreeman.com/lodish7e

- **Podcasts** narrated by the authors give students a deeper understanding of key figures in the text and a sense of the thrill of discovery.
- **More than 125 animations and research videos** show the dynamic nature of key cellular processes and important experimental techniques.
- **Classic Experiment** essays focus on classic groundbreaking experiments and explore the investigative process.
- **Online Quizzing** is provided, including multiple-choice and short answer questions.

Student Solutions Manual (ISBN:1-4641-0230-9), written by Brian Storrie of the University of Arkansas for Medical Sciences, Eric A. Wong, Richard Walker, Glenda Gillaspay, and Jill Sible of Virginia Polytechnic Institute and State University and updated by Tom Huxford of San Diego State University, Stephanie Bingham of Barry University, Brian Sato of University of California-Irvine, Steve Amato of Johns Hopkins University, Greg Kelly of University of Western Ontario, Tom Keller of Florida State University, and Elizabeth Good of University of Illinois-Urbana-Champaign, contains complete worked-out solutions to all the end-of-chapter problems in the textbook.

eBook (ISBN: 1-4641-0229-5) This customizable eBook fully integrates the complete contents of the text and its interactive media in a format that features a variety of helpful study tools, including full-text searching, note-taking, bookmarking, highlighting, and more. Easily accessible on any Internet-connected computer via a standard Web browser, the eBook enables students to take an active approach to their learning in an intuitive, easy-to-use format. Visit <http://ebooks.bfwpub.com> to learn more.

For Instructors

NEW **BioPortal for *Molecular Cell Biology*** In addition to all student resources (including NEW LearningCurve quizzing tool) and a dynamic eBook, BioPortal also includes tools for instructors. Robust gradebook and assignment features allow instructors to assign any materials to their students and monitor their progress throughout the semester. Visit <http://courses.bfwpub.com> for more information.

Companion Web Site www.whfreeman.com/lodish7e

All the student resources, plus:

- All figures and tables from the book in **JPEG and PowerPoint** formats, which instructors can edit and project section by section, allowing students to follow underlying concepts. Optimized for lecture-hall presentation, including enhanced colors, enlarged labels, and boldface type.
- **Test Bank** in editable Microsoft Word format now featuring *new and revised questions* for every chapter. The test bank is written by Brian Storrie of the University of Arkansas for Medical Sciences and Eric A. Wong, Richard Walker, Glenda Gillaspay, and Jill Sible of Virginia Polytechnic Institute and State University and revised by Cindy Klevickis of James Madison University and Greg M. Kelly of the University of Ontario.
- Additional **Analyze the Data** problems are available in PDF format.
- Lecture-ready **Personal Response System “clicker”** questions are available as Microsoft Word files and Microsoft PowerPoint slides.

Instructor's Resource CD-ROM (ISBN: 1-4292-0126-6) includes all the instructor's resources from the Web site, including all the illustrations from the text, animations, videos, test bank files, clicker questions, and the solutions manual files.

Overhead Transparency Set (ISBN: 1-4292-0477-X) contains 250 key illustrations from the text, optimized for lecture-hall presentation.

ACKNOWLEDGMENTS

In updating, revising and rewriting this book, we were given invaluable help by many colleagues. We thank the following people who generously gave of their time and expertise by making contributions to specific chapters in their areas of interest, providing us with detailed information about their courses, or by reading and commenting on one or more chapters:

David Agard, *University of California, San Francisco*
 Ravi Allada, *Northwestern University*
 Stephen Amato, *Boston College*
 James M. Anderson, *National Institutes of Health and University of North Carolina, Chapel Hill*
 Kenneth Balazovich, *University of Michigan, Ann Arbor*
 Amit Banerjee, *Wayne State University*
 Amy Bejsovec, *Duke University*
 Andrew Bendall, *University of Guelph, Ridgetown*
 Stephanie Bingham, *Barry University, Dwayne O. Andreas School of Law*
 Doug Black, *Howard Hughes Medical Institute and University of California, Los Angeles*

We would also like to express our gratitude and appreciation to Leah Haimo of the University of California, Riverside, for her development of new Analyze the Data problems, to Cindy Klevickis of James Madison University and Greg M. Kelly of the University of Ontario for their authorship of excellent new Review the Concepts problems and Test Bank questions, and to Jill Sible of Virginia Polytechnic Institute and State University for her revision of the Online Quizzing problems. We are also grateful to Lisa Rezende of the University of Arizona for her development of the Classic Experiments and Podcasts.

This edition would not have been possible without the careful and committed collaboration of our publishing partners at W. H. Freeman and Company. We thank Kate Ahr Parker, Mary Louise Byrd, Debbie Clare, Marsha Cohen,

Victoria Tomaselli, Christina Micek, Bill O'Neal, Marni Rolfes, Beth McHenry, Susan Timmins, Cecilia Varas, and Julia DeRosa for their labor and for their willingness to work overtime to produce a book that excels in every way.

In particular, we would like to acknowledge the talent and commitment of our text editors, Matthew Tontonoz, Erica Pantages Frost, and Erica Champion. They are remarkable editors. Thank you for all you've done in this edition.

We are also indebted to H. Adam Steinberg for his pedagogical insight and his development of beautiful molecular models and illustrations.

We would like to acknowledge those whose direct contributions to previous editions continue to influence in this edition; especially Ruth Steyn.

Thanks to our own staff: Sally Bittancourt, Diane Bush, Mary Anne Donovan, Carol Eng, James Evans, George Kokkinogenis, Julie Knight, Guicky Waller, Nicki Watson, and Rob Welsh.

Finally, special thanks to our families for inspiring us and for granting us the time it takes to work on such a book and to our mentors and advisers for encouraging us in our studies and teaching us much of what we know: (*Harvey Lodish*) my wife, Pamela; my children and grandchildren Heidi and Eric Steinert and Emma and Andrew Steinert; Martin Lodish, Kristin Schardt, and Sophia, Joshua, and Tobias Lodish; and Stephanie Lodish, Bruce Peabody, and Isaac and Violet Peabody; mentors Norton Zinder and Sydney Brenner; and also David Baltimore and Jim Darnell for collaborating on the first editions of this book; (*Arnold Berk*) my wife Sally, Jerry Berk, Shirley Berk, Angelina Smith, David Clayton, and Phil Sharp; (*Chris A. Kaiser*) my wife Kathy O'Neill; (*Monty Krieger*) my wife Nancy Krieger, parents I. Jay Krieger and Mildred Krieger, and children Jonathan Krieger and Joshua Krieger; my mentors Robert Stroud, Michael Brown, and Joseph Goldstein; (*Anthony Bretscher*) my wife Janice and daughters Heidi and Erika, and advisers A. Dale Kaiser and Klaus Weber; (*Hidde Ploegh*) my wife Anne Mahon; (*Angelika Amon*) my husband Johannes Weis, Theresa and Clara Weis, Gerry Fink and Frank Solomon.

CONTENTS IN BRIEF

Part I Chemical and Molecular Foundations

- 1 Molecules, Cells, and Evolution 1
- 2 Chemical Foundations 23
- 3 Protein Structure and Function 59

Part II Genetics and Molecular Biology

- 4 Basic Molecular Genetic Mechanisms 115
- 5 Molecular Genetic Techniques 171
- 6 Genes, Genomics, and Chromosomes 223
- 7 Transcriptional Control of Gene Expression 279
- 8 Post-transcriptional Gene Control 345

Part III Cell Structure and Function

- 9 Culturing, Visualizing, and Perturbing Cells 397
- 10 Biomembrane Structure 443
- 11 Transmembrane Transport of Ions and Small Molecules 473
- 12 Cellular Energetics 517
- 13 Moving Proteins into Membranes and Organelles 577
- 14 Vesicular Traffic, Secretion, and Endocytosis 627
- 15 Signal Transduction and G Protein–Coupled Receptors 673
- 16 Signaling Pathways That Control Gene Activity 721
- 17 Cell Organization and Movement I: Microfilaments 773
- 18 Cell Organization and Movement II: Microtubules and Intermediate Filaments 821
- 19 The Eukaryotic Cell Cycle 873

Part IV Cell Growth and Development

- 20 Integrating Cells Into Tissues 925
- 21 Stem Cells, Cell Asymmetry, and Cell Death 977
- 22 Nerve Cells 1019
- 23 Immunology 1059
- 24 Cancer 1113

CONTENTS

Preface

vii

Part I Chemical and Molecular Foundations

1 Molecules, Cells, and Evolution

1

1.1 The Molecules of Life

4

Proteins Give Cells Structure and Perform Most Cellular Tasks

6

Nucleic Acids Carry Coded Information for Making Proteins at the Right Time and Place

7

Phospholipids Are the Conserved Building Blocks of All Cellular Membranes

10

1.2 Genomes, Cell Architecture, and Cell Function

10

Prokaryotes Comprise True Bacteria and Archaea

10

Escherichia coli Is Widely Used in Biological Research

13

All Eukaryotic Cells Have Many of the Same Organelles and Other Subcellular Structures

13

Cellular DNA Is Packaged Within Chromosomes

15

All Eukaryotic Cells Utilize a Similar Cycle to Regulate Their Division

15

1.3 Cells into Tissues: Unicellular and Metazoan Organisms Used for Molecular Cell Biology Investigations

16

Single-Celled Eukaryotes Are Used to Study Fundamental Aspects of Eukaryotic Cell Structure and Function

16

Mutations in Yeast Led to the Identification of Key Cell Cycle Proteins

17

Multicellularity Requires Cell-Cell and Cell Matrix Adhesions

17

Tissues Are Organized into Organs

18

Body Plan and Rudimentary Tissues Form Early in Embryonic Development

18

Invertebrates, Fish, and Other Organisms Serve as Experimental Systems for Study of Human Development

19

Mice Are Frequently Used to Generate Models of Human Disease

20

Viruses Are Cellular Parasites That Are Widely Employed in Molecular Cell Biology Research

21

Genetic Diseases Elucidate Important Aspects of Cell Function

22

The Following Chapters Present Much Experimental Data That Explains How We Know What We Know About Cell Structure and Function

22

2 Chemical Foundations

23

2.1 Covalent Bonds and Noncovalent Interactions

24

The Electronic Structure of an Atom Determines the Number and Geometry of Covalent Bonds It Can Make

25

Electrons May Be Shared Equally or Unequally in Covalent Bonds

26

Covalent Bonds Are Much Stronger and More Stable Than Noncovalent Interactions

28

Ionic Interactions Are Attractions Between Oppositely Charged Ions

28

Hydrogen Bonds Are Noncovalent Interactions That Determine the Water Solubility of Uncharged Molecules

28

Van der Waals Interactions Are Weak Attractive Interactions Caused by Transient Dipoles

30

The Hydrophobic Effect Causes Nonpolar Molecules to Adhere to One Another

31

Molecular Complementarity Due to Noncovalent Interactions Leads to a Lock-and-Key Fit Between Biomolecules

32

2.2 Chemical Building Blocks of Cells

33

Amino Acids Differing Only in Their Side Chains Compose Proteins

33

Five Different Nucleotides Are Used to Build Nucleic Acids

36

Monosaccharides Covalently Assemble into Linear and Branched Polysaccharides

37

Phospholipids Associate Noncovalently to Form the Basic Bilayer Structure of Biomembranes

40

2.3 Chemical Reactions and Chemical Equilibrium

43

A Chemical Reaction Is in Equilibrium When the Rates of the Forward and Reverse Reactions Are Equal

43

The Equilibrium Constant Reflects the Extent of a Chemical Reaction

44

Chemical Reactions in Cells Are at Steady State	44	Folding of Proteins in Vivo Is Promoted by Chaperones	72
Dissociation Constants of Binding Reactions Reflect the Affinity of Interacting Molecules	44	Alternatively Folded Proteins Are Implicated in Diseases	76
Biological Fluids Have Characteristic pH Values	45	3.3 Protein Binding and Enzyme Catalysis	77
Hydrogen Ions Are Released by Acids and Taken Up by Bases	46	Specific Binding of Ligands Underlies the Functions of Most Proteins	77
Buffers Maintain the pH of Intracellular and Extracellular Fluids	47	Enzymes Are Highly Efficient and Specific Catalysts	78
2.4 Biochemical Energetics	48	An Enzyme's Active Site Binds Substrates and Carries Out Catalysis	79
Several Forms of Energy Are Important in Biological Systems	48	Serine Proteases Demonstrate How an Enzyme's Active Site Works	80
Cells Can Transform One Type of Energy into Another	49	Enzymes in a Common Pathway Are Often Physically Associated with One Another	84
The Change in Free Energy Determines If a Chemical Reaction Will Occur Spontaneously	49	3.4 Regulating Protein Function	85
The ΔG° of a Reaction Can Be Calculated from Its K_{eq}	51	Regulated Synthesis and Degradation of Proteins Is a Fundamental Property of Cells	85
The Rate of a Reaction Depends on the Activation Energy Necessary to Energize the Reactants into a Transition State	51	The Proteasome Is a Molecular Machine Used to Degrade Proteins	85
Life Depends on the Coupling of Unfavorable Chemical Reactions with Energetically Favorable Ones	52	Ubiquitin Marks Cytosolic Proteins for Degradation in Proteasomes	87
Hydrolysis of ATP Releases Substantial Free Energy and Drives Many Cellular Processes	52	Noncovalent Binding Permits Allosteric, or Cooperative, Regulation of Proteins	88
ATP Is Generated During Photosynthesis and Respiration	54	Noncovalent Binding of Calcium and GTP Are Widely Used as Allosteric Switches to Control Protein Activity	88
NAD ⁺ and FAD Couple Many Biological Oxidation and Reduction Reactions	54	Phosphorylation and Dephosphorylation Covalently Regulate Protein Activity	90
3 Protein Structure and Function	59	Ubiquitination and Deubiquitination Covalently Regulate Protein Activity	90
3.1 Hierarchical Structure of Proteins	61	Proteolytic Cleavage Irreversibly Activates or Inactivates Some Proteins	92
The Primary Structure of a Protein Is Its Linear Arrangement of Amino Acids	61	Higher-Order Regulation Includes Control of Protein Location and Concentration	92
Secondary Structures Are the Core Elements of Protein Architecture	62	3.5 Purifying, Detecting, and Characterizing Proteins	93
Tertiary Structure Is the Overall Folding of a Polypeptide Chain	64	Centrifugation Can Separate Particles and Molecules That Differ in Mass or Density	93
Different Ways of Depicting the Conformation of Proteins Convey Different Types of Information	64	Electrophoresis Separates Molecules on the Basis of Their Charge-to-Mass Ratio	94
Structural Motifs Are Regular Combinations of Secondary Structures	65	Liquid Chromatography Resolves Proteins by Mass, Charge, or Binding Affinity	96
Domains Are Modules of Tertiary Structure	67	Highly Specific Enzyme and Antibody Assays Can Detect Individual Proteins	97
Multiple Polypeptides Assemble into Quaternary Structures and Supramolecular Complexes	68	Radioisotopes Are Indispensable Tools for Detecting Biological Molecules	99
Members of Protein Families Have a Common Evolutionary Ancestor	69	Mass Spectrometry Can Determine the Mass and Sequence of Proteins	101
3.2 Protein Folding	70	Protein Primary Structure Can Be Determined by Chemical Methods and from Gene Sequences	104
Planar Peptide Bonds Limit the Shapes into Which Proteins Can Fold	71	Protein Conformation Is Determined by Sophisticated Physical Methods	104
The Amino Acid Sequence of a Protein Determines How It Will Fold	71		

3.6 Proteomics

Proteomics Is the Study of All or a Large Subset of Proteins in a Biological System

Advanced Techniques in Mass Spectrometry Are Critical to Proteomic Analysis

Part II Genetics and Molecular Biology

4 Basic Molecular Genetic Mechanisms 115

4.1 Structure of Nucleic Acids 117

A Nucleic Acid Strand Is a Linear Polymer with End-to-End Directionality

Native DNA Is a Double Helix of Complementary Antiparallel Strands

DNA Can Undergo Reversible Strand Separation

Torsional Stress in DNA Is Relieved by Enzymes

Different Types of RNA Exhibit Various Conformations Related to Their Functions

4.2 Transcription of Protein-Coding Genes and Formation of Functional mRNA 124

A Template DNA Strand Is Transcribed into a Complementary RNA Chain by RNA Polymerase

Organization of Genes Differs in Prokaryotic and Eukaryotic DNA

Eukaryotic Precursor mRNAs Are Processed to Form Functional mRNAs

Alternative RNA Splicing Increases the Number of Proteins Expressed from a Single Eukaryotic Gene

4.3 The Decoding of mRNA by tRNAs 131

Messenger RNA Carries Information from DNA in a Three-Letter Genetic Code

The Folded Structure of tRNA Promotes Its Decoding Functions

Nonstandard Base Pairing Often Occurs Between Codons and Anticodons

Amino Acids Become Activated When Covalently Linked to tRNAs

4.4 Stepwise Synthesis of Proteins on Ribosomes 136

Ribosomes are Protein-Synthesizing Machines

Methionyl-tRNA^{Met} Recognizes the AUG Start Codon

Eukaryotic Translation Initiation Usually Occurs at the First AUG Closest to the 5' End of an mRNA

During Chain Elongation Each Incoming Aminoacyl-tRNA Moves Through Three Ribosomal Sites

106	Translation Is Terminated by Release Factors When a Stop Codon Is Reached	142
106	Polysomes and Rapid Ribosome Recycling Increase the Efficiency of Translation	142
108	GTPase-Superfamily Proteins Function in Several Quality Control Steps of Translation	143
	Nonsense Mutations Cause Premature Termination of Protein Synthesis	143

4.5 DNA Replication 145

DNA Polymerases Require a Primer to Initiate Replication

Duplex DNA Is Unwound, and Daughter Strands Are Formed at the DNA Replication Fork

Several Proteins Participate in DNA Replication

DNA Replication Occurs Bidirectionally from Each Origin

4.6 DNA Repair and Recombination 151

DNA Polymerases Introduce Copying Errors and Also Correct Them

Chemical and Radiation Damage to DNA Can Lead to Mutations

High-Fidelity DNA Excision Repair Systems Recognize and Repair Damage

Base Excision Repairs T-G Mismatches and Damaged Bases

Mismatch Excision Repairs Other Mismatches and Small Insertions and Deletions

Nucleotide Excision Repairs Chemical Adducts that Distort Normal DNA Shape

Two Systems Utilize Recombination to Repair Double-Strand Breaks in DNA

Homologous Recombination Can Repair DNA Damage and Generate Genetic Diversity

4.7 Viruses: Parasites of the Cellular Genetic System 160

Most Viral Host Ranges Are Narrow

Viral Capsids Are Regular Arrays of One or a Few Types of Protein

Viruses Can Be Cloned and Counted in Plaque Assays

Lytic Viral Growth Cycles Lead to Death of Host Cells

Viral DNA Is Integrated into the Host-Cell Genome in Some Nonlytic Viral Growth Cycles

5 Molecular Genetic Techniques 171

5.1 Genetic Analysis of Mutations to Identify and Study Genes 172

Recessive and Dominant Mutant Alleles Generally Have Opposite Effects on Gene Function

Segregation of Mutations in Breeding Experiments Reveals Their Dominance or Recessivity

Conditional Mutations Can Be Used to Study Essential Genes in Yeast	175	Linkage Studies Can Map Disease Genes with a Resolution of About 1 Centimorgan	208
Recessive Lethal Mutations in Diploids Can Be Identified by Inbreeding and Maintained in Heterozygotes	176	Further Analysis Is Needed to Locate a Disease Gene in Cloned DNA	209
Complementation Tests Determine Whether Different Recessive Mutations Are in the Same Gene	177	Many Inherited Diseases Result from Multiple Genetic Defects	210
Double Mutants Are Useful in Assessing the Order in Which Proteins Function	178		
Genetic Suppression and Synthetic Lethality Can Reveal Interacting or Redundant Proteins	179	5.5 Inactivating the Function of Specific Genes in Eukaryotes	212
Genes Can Be Identified by Their Map Position on the Chromosome	180	Normal Yeast Genes Can Be Replaced with Mutant Alleles by Homologous Recombination	212
		Transcription of Genes Ligated to a Regulated Promoter Can Be Controlled Experimentally	213
5.2 DNA Cloning and Characterization	182	Specific Genes Can Be Permanently Inactivated in the Germ Line of Mice	213
Restriction Enzymes and DNA Ligases Allow Insertion of DNA Fragments into Cloning Vectors	183	Somatic Cell Recombination Can Inactivate Genes in Specific Tissues	214
<i>E. coli</i> Plasmid Vectors Are Suitable for Cloning Isolated DNA Fragments	184	Dominant-Negative Alleles Can Functionally Inhibit Some Genes	215
cDNA Libraries Represent the Sequences of Protein-Coding Genes	185	RNA Interference Causes Gene Inactivation by Destroying the Corresponding mRNA	216
cDNAs Prepared by Reverse Transcription of Cellular mRNAs Can Be Cloned to Generate cDNA Libraries	186		
DNA Libraries Can Be Screened by Hybridization to an Oligonucleotide Probe	188	6 Genes, Genomics, and Chromosomes	223
Yeast Genomic Libraries Can Be Constructed with Shuttle Vectors and Screened by Functional Complementation	188	6.1 Eukaryotic Gene Structure	225
Gel Electrophoresis Allows Separation of Vector DNA from Cloned Fragments	191	Most Eukaryotic Genes Contain Introns and Produce mRNAs Encoding Single Proteins	225
The Polymerase Chain Reaction Amplifies a Specific DNA Sequence from a Complex Mixture	192	Simple and Complex Transcription Units Are Found in Eukaryotic Genomes	225
Cloned DNA Molecules Are Sequenced Rapidly by Methods Based on PCR	195	Protein-Coding Genes May Be Solitary or Belong to a Gene Family	227
		Heavily Used Gene Products Are Encoded by Multiple Copies of Genes	229
5.3 Using Cloned DNA Fragments to Study Gene Expression	198	Nonprotein-Coding Genes Encode Functional RNAs	230
Hybridization Techniques Permit Detection of Specific DNA Fragments and mRNAs	198	6.2 Chromosomal Organization of Genes and Noncoding DNA	231
DNA Microarrays Can Be Used to Evaluate the Expression of Many Genes at One Time	199	Genomes of Many Organisms Contain Nonfunctional DNA	231
Cluster Analysis of Multiple Expression Experiments Identifies Co-regulated Genes	200	Most Simple-Sequence DNAs Are Concentrated In Specific Chromosomal Locations	232
<i>E. coli</i> Expression Systems Can Produce Large Quantities of Proteins from Cloned Genes	201	DNA Fingerprinting Depends on Differences in Length of Simple-Sequence DNAs	233
Plasmid Expression Vectors Can Be Designed for Use in Animal Cells	203	Unclassified Spacer DNA Occupies a Significant Portion of the Genome	233
		6.3 Transposable (Mobile) DNA Elements	234
5.4 Locating and Identifying Human Disease Genes	206	Movement of Mobile Elements Involves a DNA or an RNA Intermediate	235
Monogenic Diseases Show One of Three Patterns of Inheritance	206	DNA Transposons Are Present in Prokaryotes and Eukaryotes	236
DNA Polymorphisms Are Used as Markers for Linkage-Mapping of Human Mutations	207	LTR Retrotransposons Behave Like Intracellular Retroviruses	238

Non-LTR Retrotransposons Transpose by a Distinct Mechanism	240	Interphase Polytene Chromosomes Arise by DNA Amplification	269
Other Retroposed RNAs Are Found in Genomic DNA	243	Three Functional Elements Are Required for Replication and Stable Inheritance of Chromosomes	270
Mobile DNA Elements Have Significantly Influenced Evolution	243	Centromere Sequences Vary Greatly in Length and Complexity	271
6.4 Organelle DNAs	245	Addition of Telomeric Sequences by Telomerase Prevents Shortening of Chromosomes	273
Mitochondria Contain Multiple mtDNA Molecules	245		
mtDNA Is Inherited Cytoplasmically	246		
The Size, Structure, and Coding Capacity of mtDNA Vary Considerably Between Organisms	246		
Products of Mitochondrial Genes Are Not Exported	248		
Mitochondria Evolved from a Single Endosymbiotic Event Involving a <i>Rickettsia</i> -like Bacterium	249		
Mitochondrial Genetic Codes Differ from the Standard Nuclear Code	249		
Mutations in Mitochondrial DNA Cause Several Genetic Diseases in Humans	250		
Chloroplasts Contain Large DNAs Often Encoding More Than a Hundred Proteins	251		
6.5 Genomics: Genome-wide Analysis of Gene Structure and Expression	252		
Stored Sequences Suggest Functions of Newly Identified Genes and Proteins	252		
Comparison of Related Sequences from Different Species Can Give Clues to Evolutionary Relationships Among Proteins	253		
Genes Can Be Identified Within Genomic DNA Sequences	253		
The Number of Protein-Coding Genes in an Organism's Genome Is Not Directly Related to Its Biological Complexity	254		
6.6 Structural Organization of Eukaryotic Chromosomes	256		
Chromatin Exists in Extended and Condensed Forms	256		
Modifications of Histone Tails Control Chromatin Condensation and Function	258		
Nonhistone Proteins Organize Long Chromatin Loops	263		
Additional Nonhistone Proteins Regulate Transcription and Replication	265		
6.7 Morphology and Functional Elements of Eukaryotic Chromosomes	266		
Chromosome Number, Size, and Shape at Metaphase Are Species-Specific	266		
During Metaphase, Chromosomes Can Be Distinguished by Banding Patterns and Chromosome Painting	267		
Chromosome Painting and DNA Sequencing Reveal the Evolution of Chromosomes	268		
		7 Transcriptional Control of Gene Expression	279
		7.1 Control of Gene Expression in Bacteria	282
		Transcription Initiation by Bacterial RNA Polymerase Requires Association with a Sigma Factor	282
		Initiation of <i>lac</i> Operon Transcription Can Be Repressed and Activated	282
		Small Molecules Regulate Expression of Many Bacterial Genes via DNA-Binding Repressors and Activators	284
		Transcription Initiation from Some Promoters Requires Alternative Sigma Factors	285
		Transcription by σ^{54} -RNA Polymerase Is Controlled by Activators That Bind Far from the Promoter	285
		Many Bacterial Responses Are Controlled by Two-Component Regulatory Systems	285
		Control of Transcription Elongation	286
		7.2 Overview of Eukaryotic Gene Control	288
		Regulatory Elements in Eukaryotic DNA Are Found Both Close to and Many Kilobases Away from Transcription Start Sites	289
		Three Eukaryotic RNA Polymerases Catalyze Formation of Different RNAs	290
		The Largest Subunit in RNA Polymerase II Has an Essential Carboxyl-Terminal Repeat	293
		7.3 RNA Polymerase II Promoters and General Transcription Factors	295
		RNA Polymerase II Initiates Transcription at DNA Sequences Corresponding to the 5' Cap of mRNAs	295
		The TATA Box, Initiators, and CpG Islands Function as Promoters in Eukaryotic DNA	295
		General Transcription Factors Position RNA Polymerase II at Start Sites and Assist in Initiation	297
		In Vivo Transcription Initiation by RNA Polymerase II Requires Additional Proteins	301
		Elongation Factors Regulate the Initial Stages of Transcription in the Promoter-Proximal Region	301

7.4 Regulatory Sequences in Protein-Coding Genes and the Proteins Through Which They Function

Promoter-Proximal Elements Help Regulate Eukaryotic Genes	302
Distant Enhancers Often Stimulate Transcription by RNA Polymerase II	303
Most Eukaryotic Genes Are Regulated by Multiple Transcription-Control Elements	304
Footprinting and Gel-Shift Assays Detect Protein-DNA Interactions	305
Activators Promote Transcription and Are Composed of Distinct Functional Domains	305
Repressors Inhibit Transcription and Are the Functional Converse of Activators	307
DNA-Binding Domains Can Be Classified into Numerous Structural Types	308
Structurally Diverse Activation and Repression Domains Regulate Transcription	311
Transcription Factor Interactions Increase Gene-Control Options	312
Multiprotein Complexes Form on Enhancers	314

7.5 Molecular Mechanisms of Transcription Repression and Activation

Formation of Heterochromatin Silences Gene Expression at Telomeres, Near Centromeres, and in Other Regions	315
Repressors Can Direct Histone Deacetylation at Specific Genes	318
Activators Can Direct Histone Acetylation at Specific Genes	318
Chromatin-Remodeling Factors Help Activate or Repress Transcription	319
The Mediator Complex Forms a Molecular Bridge Between Activation Domains and Pol II	320
The Yeast Two-Hybrid System	321

7.6 Regulation of Transcription-Factor Activity

All Nuclear Receptors Share a Common Domain Structure	324
Nuclear-Receptor Response Elements Contain Inverted or Direct Repeats	324
Hormone Binding to a Nuclear Receptor Regulates Its Activity as a Transcription Factor	325
Metazoans Regulate the Pol II Transition from Initiation to Elongation	325
Pol II Termination Is Also Regulated	326

7.7 Epigenetic Regulation of Transcription

Epigenetic Repression by DNA Methylation	327
Histone Methylation at Other Specific Lysines Are Linked to Epigenetic Mechanisms of Gene Repression	328
Epigenetic Control by Polycomb and Trithorax Complexes	330

Noncoding RNAs Direct Epigenetic Repression in Metazoans	331
Plants and Fission Yeast Use Short RNA-Directed Methylation of Histones and DNA	333

7.8 Other Eukaryotic Transcription Systems

Transcription Initiation by Pol I and Pol III Is Analogous to That by Pol II	336
Mitochondrial and Chloroplast DNAs Are Transcribed by Organelle-Specific RNA Polymerases	338

8 Post-transcriptional Gene Control

8.1 Processing of Eukaryotic Pre-mRNA

The 5' Cap Is Added to Nascent RNAs Shortly After Transcription Initiation	348
A Diverse Set of Proteins with Conserved RNA-Binding Domains Associate with Pre-mRNAs	349
Splicing Occurs at Short, Conserved Sequences in Pre-mRNAs via Two Transesterification Reactions	351
During Splicing, snRNAs Base-Pair with Pre-mRNA	352
Spliceosomes, Assembled from snRNPs and a Pre-mRNA, Carry Out Splicing	353
Chain Elongation by RNA Polymerase II Is Coupled to the Presence of RNA-Processing Factors	356
SR Proteins Contribute to Exon Definition in Long Pre-mRNAs	356
Self-Splicing Group II Introns Provide Clues to the Evolution of snRNAs	357
3' Cleavage and Polyadenylation of Pre-mRNAs Are Tightly Coupled	358
Nuclear Exonucleases Degrade RNA That Is Processed Out of Pre-mRNAs	359

8.2 Regulation of Pre-mRNA Processing

Alternative Splicing Generates Transcripts with Different Combinations of Exons	361
A Cascade of Regulated RNA Splicing Controls <i>Drosophila</i> Sexual Differentiation	361
Splicing Repressors and Activators Control Splicing at Alternative Sites	362
RNA Editing Alters the Sequences of Some Pre-mRNAs	364

8.3 Transport of mRNA Across the Nuclear Envelope

Macromolecules Exit and Enter the Nucleus Through Nuclear Pore Complexes	365
Pre-mRNAs in Spliceosomes Are Not Exported from the Nucleus	367
HIV Rev Protein Regulates the Transport of Unspliced Viral mRNAs	368

8.4 Cytoplasmic Mechanisms of Post-transcriptional Control

Micro RNAs Repress Translation of Specific mRNAs	371
RNA Interference Induces Degradation of Precisely Complementary mRNAs	373
Cytoplasmic Polyadenylation Promotes Translation of Some mRNAs	374
Degradation of mRNAs in the Cytoplasm Occurs by Several Mechanisms	375
Protein Synthesis Can Be Globally Regulated	376
Sequence-Specific RNA-Binding Proteins Control Specific mRNA Translation	379
Surveillance Mechanisms Prevent Translation of Improperly Processed mRNAs	380
Localization of mRNAs Permits Production of Proteins at Specific Regions Within the Cytoplasm	380

8.5 Processing of rRNA and tRNA

Pre-rRNA Genes Function as Nucleolar Organizers and Are Similar in All Eukaryotes	384
Small Nucleolar RNAs Assist in Processing Pre-rRNAs	385
Self-Splicing Group I Introns Were the First Examples of Catalytic RNA	389
Pre-tRNAs Undergo Extensive Modification in the Nucleus	390
Nuclear Bodies Are Functionally Specialized Nuclear Domains	391

Part III Cell Structure and Function

9 Culturing, Visualizing, and Perturbing Cells 397

9.1 Growing Cells in Culture 398

Culture of Animal Cells Requires Nutrient-Rich Media and Special Solid Surfaces	398
Primary Cell Cultures and Cell Strains Have a Finite Life Span	399
Transformed Cells Can Grow Indefinitely in Culture	400
Flow Cytometry Separates Different Cell Types	400
Growth of Cells in Two-Dimensional and Three-Dimensional Culture Mimics the In Vivo Environment	401
Hybrid Cells Called Hybridomas Produce Abundant Monoclonal Antibodies	402

9.2 Light Microscopy: Exploring Cell Structure and Visualizing Proteins Within Cells 404

The Resolution of the Light Microscope Is About 0.2 μm	404
Phase-Contrast and Differential-Interference-Contrast Microscopy Visualize Unstained Living Cells	405

Imaging Subcellular Details Often Requires That the Samples Be Fixed, Sectioned, and Stained	408
Fluorescence Microscopy Can Localize and Quantify Specific Molecules in Live Cells	408
Determination of Intracellular Ca^{2+} and H^{+} Levels with Ion-Sensitive Fluorescent Dyes	409
Immunofluorescence Microscopy Can Detect Specific Proteins in Fixed Cells	409
Tagging with Fluorescent Proteins Allows the Visualization of Specific Proteins in Living Cells	411
Deconvolution and Confocal Microscopy Enhance Visualization of Three-Dimensional Fluorescent Objects	411
TIRF Microscopy Provides Exceptional Imaging in One Focal Plane	415
FRAP Reveals the Dynamics of Cellular Components	415
FRET Measures Distance Between Chromophores	416
Super-Resolution Microscopy Can Localize Proteins to Nanometer Accuracy	418

9.3 Electron Microscopy: High-Resolution Imaging 419

Single Molecules or Structures Can Be Imaged After a Negative Stain or Metal Shadowing	419
Cells and Tissues Are Cut into Thin Sections for Viewing by Electron Microscopy	420
Immunoelectron Microscopy Localizes Proteins at the Ultrastructural Level	421
Cryoelectron Microscopy Allows Visualization of Specimens Without Fixation or Staining	421
Scanning Electron Microscopy of Metal-Coated Specimens Reveals Surface Features	423

9.4 Isolation and Characterization of Cell Organelles 424

Organelles of the Eukaryotic Cell	424
Disruption of Cells Releases Their Organelles and Other Contents	427
Centrifugation Can Separate Many Types of Organelles	427
Organelle-Specific Antibodies Are Useful in Preparing Highly Purified Organelles	429
Proteomics Reveals the Protein Composition of Organelles	430

9.5 Perturbing Specific Cell Functions 430

Drugs Are Commonly Used in Cell Biology	430
Chemical Screens Can Identify New Specific Drugs	430
Small Interfering RNAs (siRNAs) Can Knock Down Expression of Specific Proteins	432
Genomic Screens Using siRNA in the Nematode <i>C. elegans</i>	434

CLASSIC EXPERIMENT 9.1 Separating Organelles 441

10 Biomembrane Structure 443

10.1 The Lipid Bilayer: Composition and Structural Organization 445

Phospholipids Spontaneously Form Bilayers	445
Phospholipid Bilayers Form a Sealed Compartment Surrounding an Internal Aqueous Space	446
Biomembranes Contain Three Principal Classes of Lipids	448
Most Lipids and Many Proteins Are Laterally Mobile in Biomembranes	450
Lipid Composition Influences the Physical Properties of Membranes	452
Lipid Composition Is Different in the Exoplasmic and Cytosolic Leaflets	453
Cholesterol and Sphingolipids Cluster with Specific Proteins in Membrane Microdomains	454
Cells Store Excess Lipids in Lipid Droplets	455

10.2 Membrane Proteins: Structure and Basic Functions 455

Proteins Interact with Membranes in Three Different Ways	456
Most Transmembrane Proteins Have Membrane-Spanning α Helices	456
Multiple β Strands in Porins Form Membrane-Spanning "Barrels"	460
Covalently Attached Lipids Anchor Some Proteins to Membranes	460
All Transmembrane Proteins and Glycolipids Are Asymmetrically Oriented in the Bilayer	461
Lipid-Binding Motifs Help Target Peripheral Proteins to the Membrane	462
Proteins Can Be Removed from Membranes by Detergents or High-Salt Solutions	462

10.3 Phospholipids, Sphingolipids, and Cholesterol: Synthesis and Intracellular Movement 464

Fatty Acids Are Assembled from Two-Carbon Building Blocks by Several Important Enzymes	465
Small Cytosolic Proteins Facilitate Movement of Fatty Acids	465
Fatty Acids Are Incorporated into Phospholipids Primarily on the ER Membrane	465
Flippases Move Phospholipids from One Membrane Leaflet to the Opposite Leaflet	467
Cholesterol Is Synthesized by Enzymes in the Cytosol and ER Membrane	467
Cholesterol and Phospholipids Are Transported Between Organelles by Several Mechanisms	468

11 Transmembrane Transport of Ions and Small Molecules 473

11.1 Overview of Transmembrane Transport 474

Only Gases and Small Uncharged Molecules Cross Membranes by Simple Diffusion	474
Three Main Classes of Membrane Proteins Transport Molecules and Ions Across Biomembranes	475

11.2 Facilitated Transport of Glucose and Water 477

Uniport Transport Is Faster and More Specific than Simple Diffusion	477
The Low K_m of the GLUT1 Uniporter Enables It to Transport Glucose into Most Mammalian Cells	478
The Human Genome Encodes a Family of Sugar-Transporting GLUT Proteins	479
Transport Proteins Can Be Studied Using Artificial Membranes and Recombinant Cells	480
Osmotic Pressure Causes Water to Move Across Membranes	480
Aquaporins Increase the Water Permeability of Cell Membranes	481

11.3 ATP-Powered Pumps and the Intracellular Ionic Environment 483

There are Four Main Classes of ATP-Powered Pumps	483
ATP-Powered Ion Pumps Generate and Maintain Ionic Gradients Across Cellular Membranes	485
Muscle Relaxation Depends on Ca^{2+} ATPases That Pump Ca^{2+} from the Cytosol into the Sarcoplasmic Reticulum	486
The Mechanism of Action of the Ca^{2+} Pump Is Known in Detail	486
Calmodulin Regulates the Plasma Membrane Pumps That Control Cytosolic Ca^{2+} Concentrations	487
Na^+/K^+ ATPase Maintains the Intracellular Na^+ and K^+ Concentrations in Animal Cells	489
V-Class H^+ ATPases Maintain the Acidity of Lysosomes and Vacuoles	490
ABC Proteins Export a Wide Variety of Drugs and Toxins from the Cell	491
Certain ABC Proteins "Flip" Phospholipids and Other Lipid-Soluble Substrates from One Membrane Leaflet to the Other	492
The ABC Cystic Fibrosis Transmembrane Regulator (CFTR) Is a Chloride Channel, Not a Pump	494

11.4 Nongated Ion Channels and the Resting Membrane Potential 495

Selective Movement of Ions Creates a Transmembrane Electric Gradient	495
--	-----

The Resting Membrane Potential in Animal Cells Depends Largely on the Outward Flow of K^+ Ions Through Open K^+ Channels	497
Ion Channels Are Selective for Certain Ions by Virtue of a Molecular "Selectivity Filter"	497
Patch Clamps Permit Measurement of Ion Movements Through Single Channels	499
Novel Ion Channels Can Be Characterized by a Combination of Oocyte Expression and Patch Clamping	501

11.5 Cotransport by Symporters and Antiporters

Na^+ Entry into Mammalian Cells Is Thermodynamically Favored	502
Na^+ -Linked Symporters Enable Animal Cells to Import Glucose and Amino Acids Against High Concentration Gradients	502
A Bacterial Na^+ /Amino Acid Symporter Reveals How Symport Works	504
A Na^+ -Linked Ca^{2+} Antiporter Regulates the Strength of Cardiac Muscle Contraction	504
Several Cotransporters Regulate Cytosolic pH	505
An Anion Antiporter Is Essential for Transport of CO_2 by Red Blood Cells	506
Numerous Transport Proteins Enable Plant Vacuoles to Accumulate Metabolites and Ions	507

11.6 Transcellular Transport

Multiple Transport Proteins Are Needed to Move Glucose and Amino Acids Across Epithelia	508
Simple Rehydration Therapy Depends on the Osmotic Gradient Created by Absorption of Glucose and Na^+	508
Parietal Cells Acidify the Stomach Contents While Maintaining a Neutral Cytosolic pH	509
Bone Resorption Requires Coordinated Function of a V-Class Proton Pump and a Specific Chloride Channel Protein	509

CLASSIC EXPERIMENT 11.1 Stumbling upon Active Transport 515

12 Cellular Energetics 517

12.1 First Step of Harvesting Energy from Glucose: Glycolysis 519

During Glycolysis (Stage I), Cytosolic Enzymes Convert Glucose to Pyruvate	520
The Rate of Glycolysis Is Adjusted to Meet the Cell's Need for ATP	520
Glucose Is Fermented When Oxygen Is Scarce	522

12.2 Mitochondria and the Citric Acid Cycle 524

Mitochondria Are Dynamic Organelles with Two Structurally and Functionally Distinct Membranes	524
In the First Part of Stage II, Pyruvate Is Converted to Acetyl CoA and High-Energy Electrons	526
In the Second Part of Stage II, the Citric Acid Cycle Oxidizes the Acetyl Group in Acetyl CoA to CO_2 and Generates High-Energy Electrons	527
Transporters in the Inner Mitochondrial Membrane Help Maintain Appropriate Cytosolic and Matrix Concentrations of NAD^+ and NADH	529
Mitochondrial Oxidation of Fatty Acids Generates ATP	529
Peroxisomal Oxidation of Fatty Acids Generates No ATP	531

12.3 The Electron Transport Chain and Generation of the Proton-Motive Force 532

Oxidation of NADH and $FADH_2$ Releases a Significant Amount of Energy	532
Electron Transport in Mitochondria Is Coupled to Proton Pumping	533
Electrons Flow "Downhill" Through a Series of Electron Carriers	534
Four Large Multiprotein Complexes Couple Electron Transport to Proton Pumping Across the Mitochondrial Inner Membrane	535
Reduction Potentials of Electron Carriers in the Electron Transport Chain Favor Electron Flow from NADH to O_2	539
The Multiprotein Complexes of the Electron Transport Chain Assemble into Supercomplexes	540
Reactive Oxygen Species (ROS) Are Toxic By-products of Electron Transport That Can Damage Cells	541
Experiments Using Purified Electron Transport Chain Complexes Established the Stoichiometry of Proton Pumping	542
The Proton-Motive Force in Mitochondria Is Due Largely to a Voltage Gradient Across the Inner Membrane	542

12.4 Harnessing the Proton-Motive Force to Synthesize ATP 544

The Mechanism of ATP Synthesis Is Shared Among Bacteria, Mitochondria, and Chloroplasts	544
ATP Synthase Comprises F_0 and F_1 Multiprotein Complexes	546
Rotation of the F_1 γ Subunit, Driven by Proton Movement Through F_0 , Powers ATP Synthesis	547
Multiple Protons Must Pass Through ATP Synthase to Synthesize One ATP	549
F_0 c Ring Rotation Is Driven by Protons Flowing Through Transmembrane Channels	549
ATP-ADP Exchange Across the Inner Mitochondrial Membrane Is Powered by the Proton-Motive Force	550

Rate of Mitochondrial Oxidation Normally Depends on ADP Levels	551	A Hydrophobic N-Terminal Signal Sequence Targets Nascent Secretory Proteins to the ER	580
Brown-Fat Mitochondria Use the Proton-Motive Force to Generate Heat	551	Cotranslational Translocation Is Initiated by Two GTP-Hydrolyzing Proteins	582
12.5 Photosynthesis and Light-Absorbing Pigments	552	Passage of Growing Polypeptides Through the Translocon Is Driven by Translation	583
Thylakoid Membranes in Chloroplasts Are the Sites of Photosynthesis in Plants	553	ATP Hydrolysis Powers Post-translational Translocation of Some Secretory Proteins in Yeast	584
Three of the Four Stages in Photosynthesis Occur Only During Illumination	553	13.2 Insertion of Membrane Proteins into the ER	587
Each Photon of Light Has a Defined Amount of Energy	555	Several Topological Classes of Integral Membrane Proteins Are Synthesized on the ER	587
Photosystems Comprise a Reaction Center and Associated Light-Harvesting Complexes	555	Internal Stop-Transfer and Signal-Anchor Sequences Determine Topology of Single-Pass Proteins	588
Photoelectron Transport from Energized Reaction-Center Chlorophyll <i>a</i> Produces a Charge Separation	556	Multipass Proteins Have Multiple Internal Topogenic Sequences	591
Internal Antenna and Light-Harvesting Complexes Increase the Efficiency of Photosynthesis	557	A Phospholipid Anchor Tethers Some Cell-Surface Proteins to the Membrane	592
12.6 Molecular Analysis of Photosystems	559	The Topology of a Membrane Protein Often Can Be Deduced from Its Sequence	592
The Single Photosystem of Purple Bacteria Generates a Proton-Motive Force but No O ₂	559	13.3 Protein Modifications, Folding, and Quality Control in the ER	594
Chloroplasts Contain Two Functionally and Spatially Distinct Photosystems	561	A Preformed N-Linked Oligosaccharide Is Added to Many Proteins in the Rough ER	595
Linear Electron Flow Through Both Plant Photosystems, PSII and PSI, Generates a Proton-Motive Force, O ₂ , and NADPH	561	Oligosaccharide Side Chains May Promote Folding and Stability of Glycoproteins	596
An Oxygen-Evolving Complex Is Located on the Luminal Surface of the PSII Reaction Center	562	Disulfide Bonds Are Formed and Rearranged by Proteins in the ER Lumen	596
Multiple Mechanisms Protect Cells Against Damage from Reactive Oxygen Species During Photoelectron Transport	563	Chaperones and Other ER Proteins Facilitate Folding and Assembly of Proteins	598
Cyclic Electron Flow Through PSI Generates a Proton-Motive Force but No NADPH or O ₂	564	Improperly Folded Proteins in the ER Induce Expression of Protein-Folding Catalysts	599
Relative Activities of Photosystems I and II Are Regulated	565	Unassembled or Misfolded Proteins in the ER Are Often Transported to the Cytosol for Degradation	600
12.7 CO₂ Metabolism During Photosynthesis	567	13.4 Targeting of Proteins to Mitochondria and Chloroplasts	601
Rubisco Fixes CO ₂ in the Chloroplast Stroma	567	Amphipathic N-Terminal Signal Sequences Direct Proteins to the Mitochondrial Matrix	603
Synthesis of Sucrose Using Fixed CO ₂ Is Completed in the Cytosol	567	Mitochondrial Protein Import Requires Outer-Membrane Receptors and Translocons in Both Membranes	603
Light and Rubisco Activase Stimulate CO ₂ Fixation	569	Studies with Chimeric Proteins Demonstrate Important Features of Mitochondrial Import	605
Photorespiration Competes with Carbon Fixation and Is Reduced in C ₄ Plants	569	Three Energy Inputs Are Needed to Import Proteins into Mitochondria	606
13 Moving Proteins into Membranes and Organelles	577	Multiple Signals and Pathways Target Proteins to Submitochondrial Compartments	606
13.1 Targeting Proteins to and Across the ER Membrane	579	Targeting of Chloroplast Stromal Proteins Is Similar to Import of Mitochondrial Matrix Proteins	610
Pulse-Labeling Experiments with Purified ER Membranes Demonstrated That Secreted Proteins Cross the ER Membrane	579		

Proteins Are Targeted to Thylakoids by Mechanisms Related to Translocation Across the Bacterial Cytoplasmic Membrane	610	Anterograde Transport Through the Golgi Occurs by Cisternal Maturation	643
13.5 Targeting of Peroxisomal Proteins	612	14.4 Later Stages of the Secretory Pathway	646
Cytosolic Receptor Targets Proteins with an SKL Sequence at the C-Terminus into the Peroxisomal Matrix	612	Vesicles Coated with Clathrin and/or Adapter Proteins Mediate Transport from the <i>trans</i> -Golgi	646
Peroxisomal Membrane and Matrix Proteins Are Incorporated by Different Pathways	613	Dynamin Is Required for Pinching Off of Clathrin Vesicles	647
13.6 Transport into and out of the Nucleus	615	Mannose 6-Phosphate Residues Target Soluble Proteins to Lysosomes	648
Large and Small Molecules Enter and Leave the Nucleus via Nuclear Pore Complexes	615	Study of Lysosomal Storage Diseases Revealed Key Components of the Lysosomal Sorting Pathway	649
Nuclear Transport Receptors Escort Proteins Containing Nuclear-Localization Signals into the Nucleus	617	Protein Aggregation in the <i>trans</i> -Golgi May Function in Sorting Proteins to Regulated Secretory Vesicles	651
A Second Type of Nuclear Transport Receptors Escort Proteins Containing Nuclear-Export Signals out of the Nucleus	619	Some Proteins Undergo Proteolytic Processing After Leaving the <i>trans</i> -Golgi	651
Most mRNAs Are Exported from the Nucleus by a Ran-Independent Mechanism	619	Several Pathways Sort Membrane Proteins to the Apical or Basolateral Region of Polarized Cells	652
14 Vesicular Traffic, Secretion, and Endocytosis	627	14.5 Receptor-Mediated Endocytosis	654
14.1 Techniques for Studying the Secretory Pathway	629	Cells Take Up Lipids from the Blood in the Form of Large, Well-Defined Lipoprotein Complexes	656
Transport of a Protein Through the Secretory Pathway Can Be Assayed in Living Cells	629	Receptors for Low-Density Lipoprotein and Other Ligands Contain Sorting Signals That Target Them for Endocytosis	657
Yeast Mutants Define Major Stages and Many Components in Vesicular Transport	632	The Acidic pH of Late Endosomes Causes Most Receptor-Ligand Complexes to Dissociate	658
Cell-Free Transport Assays Allow Dissection of Individual Steps in Vesicular Transport	633	The Endocytic Pathway Delivers Iron to Cells Without Dissociation of the Receptor-Transferrin Complex in Endosomes	659
14.2 Molecular Mechanisms of Vesicle Budding and Fusion	634	14.6 Directing Membrane Proteins and Cytosolic Materials to the Lysosome	661
Assembly of a Protein Coat Drives Vesicle Formation and Selection of Cargo Molecules	634	Multivesicular Endosomes Segregate Membrane Proteins Destined for the Lysosomal Membrane from Proteins Destined for Lysosomal Degradation	661
A Conserved Set of GTPase Switch Proteins Controls Assembly of Different Vesicle Coats	635	Retroviruses Bud from the Plasma Membrane by a Process Similar to Formation of Multivesicular Endosomes	663
Targeting Sequences on Cargo Proteins Make Specific Molecular Contacts with Coat Proteins	636	The Autophagic Pathway Delivers Cytosolic Proteins or Entire Organelles to Lysosomes	664
Rab GTPases Control Docking of Vesicles on Target Membranes	638	CLASSIC EXPERIMENT 14.1 Following a Protein Out of the Cell	671
Paired Sets of SNARE Proteins Mediate Fusion of Vesicles with Target Membranes	639	15 Signal Transduction and G Protein-Coupled Receptors	673
Dissociation of SNARE Complexes After Membrane Fusion Is Driven by ATP Hydrolysis	639	15.1 Signal Transduction: From Extracellular Signal to Cellular Response	675
14.3 Early Stages of the Secretory Pathway	640	Signaling Molecules Can Act Locally or at a Distance	675
COPII Vesicles Mediate Transport from the ER to the Golgi	640	Binding of Signaling Molecules Activates Receptors on Target Cells	676
COPI Vesicles Mediate Retrograde Transport Within the Golgi and from the Golgi to the ER	642		

Protein Kinases and Phosphatases Are Employed in Virtually All Signaling Pathways	677	Structural Studies Established How $G_{i\alpha s}$ · GTP Binds to and Activates Adenylyl Cyclase	700
GTP-Binding Proteins Are Frequently Used in Signal Transduction as On/Off Switches	678	cAMP Activates Protein Kinase A by Releasing Inhibitory Subunits	701
Intracellular “Second Messengers” Transmit and Amplify Signals from Many Receptors	679	Glycogen Metabolism Is Regulated by Hormone-Induced Activation of Protein Kinase A	701
15.2 Studying Cell-Surface Receptors and Signal Transduction Proteins	681	cAMP-Mediated Activation of Protein Kinase A Produces Diverse Responses in Different Cell Types	702
The Dissociation Constant Is a Measure of the Affinity of a Receptor for Its Ligand	681	Signal Amplification Occurs in the cAMP–Protein Kinase A Pathway	703
Binding Assays Are Used to Detect Receptors and Determine Their Affinity and Specificity for Ligands	682	CREB Links cAMP and Protein Kinase A to Activation of Gene Transcription	703
Maximal Cellular Response to a Signaling Molecule Usually Does Not Require Activation of All Receptors	683	Anchoring Proteins Localize Effects of cAMP to Specific Regions of the Cell	704
Sensitivity of a Cell to External Signals Is Determined by the Number of Surface Receptors and Their Affinity for Ligand	684	Multiple Mechanisms Down-Regulate Signaling from the GPCR/cAMP/PKA Pathway	705
Receptors Can Be Purified by Affinity Techniques	685	15.6 G Protein–Coupled Receptors That Trigger Elevations in Cytosolic Ca^{2+}	707
Immunoprecipitation Assays and Affinity Techniques Can Be Used to Study the Activity of Signal Transduction Proteins	685	Activated Phospholipase C Generates Two Key Second Messengers Derived from the Membrane Lipid Phosphatidylinositol	708
15.3 G Protein–Coupled Receptors: Structure and Mechanism	687	The Ca^{2+} –Calmodulin Complex Mediates Many Cellular Responses to External Signals	711
All G Protein–Coupled Receptors Share the Same Basic Structure	687	Signal-Induced Relaxation of Vascular Smooth Muscle Is Mediated by a Ca^{2+} –Nitric Oxide–cGMP-Activated Protein Kinase G Pathway	711
Ligand-Activated G Protein–Coupled Receptors Catalyze Exchange of GTP for GDP on the α Subunit of a Trimeric G Protein	687	Integration of Ca^{2+} and cAMP Second Messengers Regulates Glycogenolysis	711
Different G Proteins Are Activated by Different GPCRs and In Turn Regulate Different Effector Proteins	689	CLASSIC EXPERIMENT 15.1 The Infancy of Signal Transduction—GTP Stimulation of cAMP Synthesis	719
15.4 G Protein–Coupled Receptors That Regulate Ion Channels	693	16 Signaling Pathways That Control Gene Expression	721
Acetylcholine Receptors in the Heart Muscle Activate a G Protein That Opens K^+ Channels	693	16.1 Receptors That Activate Protein Tyrosine Kinases	723
Light Activates G Protein–Coupled Rhodopsins in Rod Cells of the Eye	694	Numerous Factors Regulating Cell Division and Metabolism Are Ligands for Receptor Tyrosine Kinases	723
Activation of Rhodopsin by Light Leads to Closing of cGMP-Gated Cation Channels	695	Binding of Ligand Promotes Dimerization of an RTK and Leads to Activation of Its Intrinsic Kinase	724
Signal Amplification Makes the Rhodopsin Signal Transduction Pathway Exquisitely Sensitive	696	Homo- and Hetero-oligomers of Epidermal Growth Factor Receptors Bind Members of the Epidermal Growth Factor Superfamily	726
Rapid Termination of the Rhodopsin Signal Transduction Pathway Is Essential for Acute Vision	696	Cytokines Influence Development of Many Cell Types	728
Rod Cells Adapt to Varying Levels of Ambient Light by Intracellular Trafficking of Arrestin and Transducin	698	Binding of a Cytokine to Its Receptor Activates a Tightly Bound JAK Protein Tyrosine Kinase	728
15.5 G Protein–Coupled Receptors That Activate or Inhibit Adenylyl Cyclase	699	Phosphotyrosine Residues Are Binding Surfaces for Multiple Proteins with Conserved Domains	730
Adenylyl Cyclase Is Stimulated and Inhibited by Different Receptor–Ligand Complexes	699		

SH2 Domains in Action: JAK Kinases Activate STAT Transcription Factors	730	Hedgehog Signaling Relieves Repression of Target Genes	753
Multiple Mechanisms Down-Regulate Signaling from RTKs and Cytokine Receptors	731	Hedgehog Signaling in Vertebrates Involves Primary Cilia	755
16.2 The Ras/MAP Kinase Pathway	734	Degradation of an Inhibitor Protein Activates the NF- κ B Transcription Factor	757
Ras, a GTPase Switch Protein, Operates Downstream of Most RTKs and Cytokine Receptors	735	Polyubiquitin Chains Serve as Scaffolds Linking Receptors to Downstream Proteins in the NF- κ B Pathway	759
Genetic Studies in <i>Drosophila</i> Identified Key Signal-Transducing Proteins in the Ras/MAP Kinase Pathway	735	16.6 Signaling Pathways Controlled by Protein Cleavage: Notch/Delta, SREBP	760
Receptor Tyrosine Kinases and JAK Kinases Are Linked to Ras by Adapter Proteins	737	On Binding Delta, the Notch Receptor Is Cleaved, Releasing a Component Transcription Factor	760
Binding of Sos to Inactive Ras Causes a Conformational Change That Triggers an Exchange of GTP for GDP	738	Matrix Metalloproteases Catalyze Cleavage of Many Signaling Proteins from the Cell Surface	761
Signals Pass from Activated Ras to a Cascade of Protein Kinases, Ending with MAP Kinase	738	Inappropriate Cleavage of Amyloid Precursor Protein Can Lead to Alzheimer's Disease	762
Phosphorylation of MAP Kinase Results in a Conformational Change That Enhances Its Catalytic Activity and Promotes Kinase Dimerization	740	Regulated Intramembrane Proteolysis of SREBP Releases a Transcription Factor That Acts to Maintain Phospholipid and Cholesterol Levels	762
MAP Kinase Regulates the Activity of Many Transcription Factors Controlling Early Response Genes	741	16.7 Integration of Cellular Responses to Multiple Signaling Pathways	765
G Protein-Coupled Receptors Transmit Signals to MAP Kinase in Yeast Mating Pathways	742	Insulin and Glucagon Work Together to Maintain a Stable Blood Glucose Level	765
Scaffold Proteins Separate Multiple MAP Kinase Pathways in Eukaryotic Cells	744	Multiple Signal Transduction Pathways Interact to Regulate Adipocyte Differentiation Through PPAR γ , the Master Transcriptional Regulator	767
16.3 Phosphoinositide Signaling Pathways	745	17 Cell Organization and Movement I: Microfilaments	773
Phospholipase C γ Is Activated by Some RTKs and Cytokine Receptors	745	17.1 Microfilaments and Actin Structures	776
Recruitment of PI-3 Kinase to Activated Receptors Leads to Synthesis of Three Phosphorylated Phosphatidylinositols	745	Actin Is Ancient, Abundant, and Highly Conserved	776
Accumulation of PI 3-Phosphates in the Plasma Membrane Leads to Activation of Several Kinases	746	G-Actin Monomers Assemble into Long, Helical F-Actin Polymers	777
Activated Protein Kinase B Induces Many Cellular Responses	747	F-Actin Has Structural and Functional Polarity	778
The PI-3 Kinase Pathway Is Negatively Regulated by PTEN Phosphatase	747	17.2 Dynamics of Actin Filaments	779
16.4 Receptor Serine Kinases That Activate Smads	748	Actin Polymerization in Vitro Proceeds in Three Steps	779
Three Separate TGF- β Receptor Proteins Participate in Binding TGF- β and Activating Signal Transduction	748	Actin Filaments Grow Faster at (+) Ends Than at (-) Ends	779
Activated TGF- β Receptors Phosphorylate Smad Transcription Factors	749	Actin Filament Treadmilling Is Accelerated by Profilin and Cofilin	782
Negative Feedback Loops Regulate TGF- β /Smad Signaling	751	Thymosin- β_4 Provides a Reservoir of Actin for Polymerization	782
16.5 Signaling Pathways Controlled by Ubiquitination: Wnt, Hedgehog, and NF-κB	752	Capping Proteins Block Assembly and Disassembly at Actin Filament Ends	783
Wnt Signaling Triggers Release of a Transcription Factor from a Cytosolic Protein Complex	752	17.3 Mechanisms of Actin Filament Assembly	784
		Formins Assemble Unbranched Filaments	784
		The Arp2/3 Complex Nucleates Branched Filament Assembly	785

Intracellular Movements Can Be Powered by Actin Polymerization	787
Microfilaments Function in Endocytosis	788
Toxins That Perturb the Pool of Actin Monomers Are Useful for Studying Actin Dynamics	789

17.4 Organization of Actin-Based Cellular Structures 790

Cross-Linking Proteins Organize Actin Filaments into Bundles or Networks	790
Adaptor Proteins Link Actin Filaments to Membranes	791

17.5 Myosins: Actin-Based Motor Proteins 793

Myosins Have Head, Neck, and Tail Domains with Distinct Functions	794
Myosins Make Up a Large Family of Mechanochemical Motor Proteins	796
Conformational Changes in the Myosin Head Couple ATP Hydrolysis to Movement	797
Myosin Heads Take Discrete Steps Along Actin Filaments	799
Myosin V Walks Hand over Hand down an Actin Filament	799

17.6 Myosin-Powered Movements 801

Myosin Thick Filaments and Actin Thin Filaments in Skeletal Muscle Slide Past One Another During Contraction	801
Skeletal Muscle Is Structured by Stabilizing and Scaffolding Proteins	802
Contraction of Skeletal Muscle Is Regulated by Ca^{2+} and Actin-Binding Proteins	802
Actin and Myosin II Form Contractile Bundles in Nonmuscle Cells	804
Myosin-Dependent Mechanisms Regulate Contraction in Smooth Muscle and Nonmuscle Cells	804
Myosin-V-Bound Vesicles Are Carried Along Actin Filaments	805

17.7 Cell Migration: Mechanism, Signaling, and Chemotaxis 808

Cell Migration Coordinates Force Generation with Cell Adhesion and Membrane Recycling	808
The Small GTP-Binding Proteins Cdc42, Rac, and Rho Control Actin Organization	810
Cell Migration Involves the Coordinate Regulation of Cdc42, Rac, and Rho	812
Migrating Cells Are Steered by Chemotactic Molecules	813
Chemotactic Gradients Induce Altered Phosphoinositide Levels Between the Front and Back of a Cell	814

CLASSIC EXPERIMENT 17.1 Looking at Muscle Contraction 819

18 Cell Organization and Movement II: Microtubules and Intermediate Filaments 821

18.1 Microtubule Structure and Organization 822

Microtubule Walls Are Polarized Structures Built from $\alpha\beta$ -Tubulin Dimers	822
Microtubules Are Assembled from MTOCs to Generate Diverse Organizations	824

18.2 Microtubule Dynamics 827

Individual Microtubules Exhibit Dynamic Instability	827
Localized Assembly and "Search-and-Capture" Help Organize Microtubules	829
Drugs Affecting Tubulin Polymerization Are Useful Experimentally and in Treatment of Diseases	829

18.3 Regulation of Microtubule Structure and Dynamics 830

Microtubules Are Stabilized by Side-Binding Proteins	830
+ TIPs Regulate the Properties and Functions of the Microtubule (+) End	831
Other End-Binding Proteins Regulate Microtubule Disassembly	831

18.4 Kinesins and Dyneins: Microtubule-Based Motor Proteins 833

Organelles in Axons Are Transported Along Microtubules in Both Directions	833
Kinesin-1 Powers Anterograde Transport of Vesicles Down Axons Toward the (+) End of Microtubules	834
Kinesins Form a Large Protein Family with Diverse Functions	836
Kinesin-1 Is a Highly Processive Motor	837
Dynein Motors Transport Organelles Toward the (–) End of Microtubules	837
Kinesins and Dyneins Cooperate in the Transport of Organelles Throughout the Cell	841
Tubulin Modifications Distinguish Different Microtubules and Their Accessibility to Motors	842

18.5 Cilia and Flagella: Microtubule-Based Surface Structures 844

Eukaryotic Cilia and Flagella Contain Long Doublet Microtubules Bridged by Dynein Motors	845
Ciliary and Flagellar Beating Are Produced by Controlled Sliding of Outer Doublet Microtubules	845
Intraflagellar Transport Moves Material up and down Cilia and Flagella	846

Primary Cilia Are Sensory Organelles on Interphase Cells	847	Cyclin-Dependent Kinases Control the Eukaryotic Cell Cycle	876
Defects in Primary Cilia Underlie Many Diseases	848	Several Key Principles Govern the Cell Cycle	876
18.6 Mitosis	849	19.2 Model Organisms and Methods to Study the Cell Cycle	877
Centrosomes Duplicate Early in the Cell Cycle in Preparation for Mitosis	849	Budding and Fission Yeast Are Powerful Systems for Genetic Analysis of the Cell Cycle	877
Mitosis Can Be Divided into Six Phases	849	Frog Oocytes and Early Embryos Facilitate Biochemical Characterization of the Cell Cycle Engine	878
The Mitotic Spindle Contains Three Classes of Microtubules	851	Fruit Flies Reveal the Interplay Between Development and the Cell Cycle	880
Microtubule Dynamics Increase Dramatically in Mitosis	851	The Study of Tissue Culture Cells Uncovers Cell Cycle Regulation in Mammals	881
Mitotic Asters Are Pushed Apart by Kinesin-5 and Oriented by Dynein	852	Researchers Use Multiple Tools to Study the Cell Cycle	881
Chromosomes Are Captured and Oriented During Prometaphase	852	19.3 Regulation of CDK Activity	883
Duplicated Chromosomes Are Aligned by Motors and Microtubule Dynamics	855	Cyclin-Dependent Kinases Are Small Protein Kinases That Require a Regulatory Cyclin Subunit for Their Activity	884
The Chromosomal Passenger Complex Regulates Microtubule Attachment at Kinetochores	855	Cyclins Determine the Activity of CDKs	885
Anaphase A Moves Chromosomes to Poles by Microtubule Shortening	856	Cyclin Levels Are Primarily Regulated by Protein Degradation	887
Anaphase B Separates Poles by the Combined Action of Kinesins and Dynein	857	CDKs Are Regulated by Activating and Inhibitory Phosphorylation	888
Additional Mechanisms Contribute to Spindle Formation	858	CDK Inhibitors Control Cyclin-CDK Activity	888
Cytokinesis Splits the Duplicated Cell in Two	858	Special CDK Alleles Led to the Discovery of CDK Functions	889
Plant Cells Reorganize Their Microtubules and Build a New Cell Wall in Mitosis	859	19.4 Commitment to the Cell Cycle and DNA Replication	890
18.7 Intermediate Filaments	860	Cells Are Irreversibly Committed to Cell Division at a Cell Cycle Point Called START	890
Intermediate Filaments Are Assembled from Subunit Dimers	861	The E2F Transcription Factor and Its Regulator Rb Control the G ₁ -S Phase Transition in Metazoans	891
Intermediate Filament Proteins Are Expressed in a Tissue-Specific Manner	862	Extracellular Signals Govern Cell Cycle Entry	892
Intermediate Filaments Are Dynamic	863	Degradation of an S Phase CDK Inhibitor Triggers DNA Replication	892
Defects in Lamins and Keratins Cause Many Diseases	863	Replication at Each Origin Is Initiated Once and Only Once During the Cell Cycle	894
18.8 Coordination and Cooperation Between Cytoskeletal Elements	865	Duplicated DNA Strands Become Linked During Replication	896
Intermediate Filament-Associated Proteins Contribute to Cellular Organization	865	19.5 Entry into Mitosis	897
Microfilaments and Microtubules Cooperate to Transport Melanosomes	865	Precipitous Activation of Mitotic CDKs Initiates Mitosis	897
Cdc42 Coordinates Microtubules and Microfilaments During Cell Migration	866	Mitotic CDKs Promote Nuclear Envelope Breakdown	898
Advancement of Neural Growth Cones Is Coordinated by Microfilaments and Microtubules	866	Mitotic CDKs Promote Mitotic Spindle Formation	899
19 The Eukaryotic Cell Cycle	873	Chromosome Condensation Facilitates Chromosome Segregation	901
19.1 Overview of the Cell Cycle and Its Control	875	19.6 Completion of Mitosis: Chromosome Segregation and Exit from Mitosis	903
The Cell Cycle Is an Ordered Series of Events Leading to Cell Replication	875	Separase-Mediated Cleavage of Cohesins Initiates Chromosome Segregation	903

The APC/C Activates Separase Through Securin Ubiquitylation	903
Mitotic CDK Inactivation Triggers Exit from Mitosis	904
Cytokinesis Creates Two Daughter Cells	905

19.7 Surveillance Mechanisms in Cell Cycle Regulation 906

Checkpoint Pathways Establish Dependencies and Prevent Errors in the Cell Cycle	907
The Growth Checkpoint Pathway Ensures That Cells Only Enter the Cell Cycle After Sufficient Macromolecule Biosynthesis	907
The DNA Damage Response Halts Cell Cycle Progression When DNA Is Compromised	908
The Spindle Assembly Checkpoint Pathway Prevents Chromosome Segregation Until Chromosomes Are Accurately Attached to the Mitotic Spindle	910
The Spindle Position Checkpoint Pathway Ensures That the Nucleus Is Accurately Partitioned Between Two Daughter Cells	912

19.8 Meiosis: A Special Type of Cell Division 913

Extracellular and Intracellular Cues Regulate Entry into Meiosis	913
Several Key Features Distinguish Meiosis from Mitosis	915
Recombination and a Meiosis-Specific Cohesin Subunit Are Necessary for the Specialized Chromosome Segregation in Meiosis I	915
Co-orienting Sister Kinetochores Is Critical for Meiosis I Chromosome Segregation	918
DNA Replication Is Inhibited Between the Two Meiotic Divisions	918

CLASSIC EXPERIMENT 19.1 Cell Biology Emerging from the Sea: The Discovery of Cyclins 923

Part IV Cell Growth and Development

20 Integrating Cells Into Tissues 925

20.1 Cell-Cell and Cell-Matrix Adhesion: An Overview 927

Cell-Adhesion Molecules Bind to One Another and to Intracellular Proteins	927
The Extracellular Matrix Participates in Adhesion, Signaling, and Other Functions	929
The Evolution of Multifaceted Adhesion Molecules Made Possible the Evolution of Diverse Animal Tissues	932

20.2 Cell-Cell and Cell-ECM Junctions and Their Adhesion Molecules 933

Epithelial Cells Have Distinct Apical, Lateral, and Basal Surfaces	933
Three Types of Junctions Mediate Many Cell-Cell and Cell-ECM Interactions	934
Cadherins Mediate Cell-Cell Adhesions in Adherens Junctions and Desmosomes	935
Integrins Mediate Cell-ECM Adhesions, Including Those in Epithelial Cell Hemidesmosomes	939
Tight Junctions Seal Off Body Cavities and Restrict Diffusion of Membrane Components	940
Gap Junctions Composed of Connexins Allow Small Molecules to Pass Directly Between Adjacent Cells	943

20.3 The Extracellular Matrix I: The Basal Lamina 945

The Basal Lamina Provides a Foundation for Assembly of Cells into Tissues	946
Laminin, a Multi-adhesive Matrix Protein, Helps Cross-link Components of the Basal Lamina	947
Sheet-Forming Type IV Collagen Is a Major Structural Component of the Basal Lamina	947
Perlecan, a Proteoglycan, Cross-links Components of the Basal Lamina and Cell-Surface Receptors	950

20.4 The Extracellular Matrix II: Connective Tissue 951

Fibrillar Collagens Are the Major Fibrous Proteins in the ECM of Connective Tissues	951
Fibrillar Collagen Is Secreted and Assembled into Fibrils Outside the Cell	952
Type I and II Collagens Associate with Nonfibrillar Collagens to Form Diverse Structures	953
Proteoglycans and Their Constituent GAGs Play Diverse Roles in the ECM	954
Hyaluronan Resists Compression, Facilitates Cell Migration, and Gives Cartilage Its Gel-like Properties	956
Fibronectins Interconnect Cells and Matrix, Influencing Cell Shape, Differentiation, and Movement	957
Elastic Fibers Permit Many Tissues to Undergo Repeated Stretching and Recoiling	959
Metalloproteases Remodel and Degrade the Extracellular Matrix	960

20.5 Adhesive Interactions in Motile and Nonmotile Cells 961

Integrins Relay Signals between Cells and Their Three-Dimensional Environment	961
Regulation of Integrin-Mediated Adhesion and Signaling Controls Cell Movement	962
Connections Between the ECM and Cytoskeleton Are Defective in Muscular Dystrophy	964

IgCAMs Mediate Cell-Cell Adhesion in Neuronal and Other Tissues	965	The Par Proteins and Other Polarity Complexes Are Involved in Epithelial-Cell Polarity	1001
Leukocyte Movement into Tissues Is Orchestrated by a Precisely Timed Sequence of Adhesive Interactions	965	The Planar Cell Polarity Pathway Orients Cells within an Epithelium	1002
20.6 Plant Tissues	967	The Par Proteins Are Also Involved in Asymmetric Cell Division of Stem Cells	1004
The Plant Cell Wall Is a Laminate of Cellulose Fibrils in a Matrix of Glycoproteins	968	21.4 Cell Death and Its Regulation	1006
Loosening of the Cell Wall Permits Plant Cell Growth	969	Programmed Cell Death Occurs Through Apoptosis	1007
Plasmodesmata Directly Connect the Cytosols of Adjacent Cells in Higher Plants	969	Evolutionarily Conserved Proteins Participate in the Apoptotic Pathway	1007
Only a Few Adhesive Molecules Have Been Identified in Plants	970	Caspases Amplify the Initial Apoptotic Signal and Destroy Key Cellular Proteins	1009
		Neurotrophins Promote Survival of Neurons	1010
21 Stem Cells, Cell Asymmetry, and Cell Death	977	Mitochondria Play a Central Role in Regulation of Apoptosis in Vertebrate Cells	1011
21.1 Early Metazoan Development and Embryonic Stem Cells	979	The Pro-apoptotic Proteins Bax and Bak Form Pores in the Outer Mitochondrial Membrane	1013
Fertilization Unifies the Genome	979	Release of Cytochrome c and SMAC/DIABLO Proteins from Mitochondria Leads to Formation of the Apoptosome and Caspase Activation	1013
Cleavage of the Mammalian Embryo Leads to the First Differentiation Events	979	Trophic Factors Induce Inactivation of Bad, a Pro-apoptotic BH3-Only Protein	1013
The Inner Cell Mass Is the Source of Embryonic Stem (ES) Cells	981	Vertebrate Apoptosis Is Regulated by BH3-Only Pro-Apoptotic Proteins That Are Activated by Environmental Stresses	1014
Multiple Factors Control the Pluripotency of ES Cells	983	Tumor Necrosis Factor and Related Death Signals Promote Cell Murder by Activating Caspases	1015
Animal Cloning Shows That Differentiation Can Be Reversed	984		
Somatic Cells Can Generate Induced Pluripotent Stem (iPS) Cells	984		
21.2 Stem Cells and Niches in Multicellular Organisms	986	22 Nerve Cells	1019
Stem Cells Give Rise to Both Stem Cells and Differentiating Cells	986	22.1 Neurons and Glia: Building Blocks of the Nervous System	1020
Stem Cells for Different Tissues Occupy Sustaining Niches	986	Information Flows Through Neurons from Dendrites to Axons	1020
Germ-Line Stem Cells Produce Sperm and Oocytes	987	Information Moves Along Axons as Pulses of Ion Flow Called Action Potentials	1021
Intestinal Stem Cells Continuously Generate All of the Cells of the Intestinal Epithelium	988	Information Flows Between Neurons via Synapses	1022
Neural Stem Cells Form Nerve and Glial Cells in the Central Nervous System	991	The Nervous System Uses Signaling Circuits Composed of Multiple Neurons	1022
Hematopoietic Stem Cells Form All Blood Cells	993	Glial Cells Form Myelin Sheaths and Support Neurons	1023
Meristems Are Niches for Stem Cells in Plants	995	22.2 Voltage-Gated Ion Channels and the Propagation of Action Potentials	1025
21.3 Mechanisms of Cell Polarity and Asymmetric Cell Division	997	The Magnitude of the Action Potential Is Close to E_{Na} and Is Caused by Na^+ Influx Through Open Na^+ Channels	1025
Cell Polarization and Asymmetry Before Cell Division Follow a Common Hierarchy	998	Sequential Opening and Closing of Voltage-Gated Na^+ and K^+ Channels Generate Action Potentials	1025
Polarized Membrane Traffic Allows Yeast to Grow Asymmetrically During Mating	998	Action Potentials Are Propagated Unidirectionally Without Diminution	1029
The Par Proteins Direct Cell Asymmetry in the Nematode Embryo	998		

Nerve Cells Can Conduct Many Action Potentials in the Absence of ATP	1029	Mechanical and Chemical Boundaries Form a First Layer of Defense Against Pathogens	1062
Voltage-Sensing S4 α Helices Move in Response to Membrane Depolarization	1030	Innate Immunity Provides a Second Line of Defense After Mechanical and Chemical Barriers Are Crossed	1062
Movement of the Channel-Inactivating Segment into the Open Pore Blocks Ion Flow	1032	Inflammation Is a Complex Response to Injury That Encompasses Both Innate and Adaptive Immunity	1065
Myelination Increases the Velocity of Impulse Conduction	1032	Adaptive Immunity, the Third Line of Defense, Exhibits Specificity	1066
Action Potentials "Jump" from Node to Node in Myelinated Axons	1033		
Two Types of Glia Produce Myelin Sheaths	1033	23.2 Immunoglobulins: Structure and Function	1068
22.3 Communication at Synapses	1036	Immunoglobulins Have a Conserved Structure Consisting of Heavy and Light Chains	1068
Formation of Synapses Requires Assembly of Presynaptic and Postsynaptic Structures	1037	Multiple Immunoglobulin Isotypes Exist, Each with Different Functions	1068
Neurotransmitters Are Transported into Synaptic Vesicles by H ⁺ -Linked Antiport Proteins	1038	Each B Cell Produces a Unique, Clonally Distributed Immunoglobulin	1069
Synaptic Vesicles Loaded with Neurotransmitter Are Localized near the Plasma Membrane	1039	Immunoglobulin Domains Have a Characteristic Fold Composed of Two β Sheets Stabilized by a Disulfide Bond	1071
Influx of Ca ²⁺ Triggers Release of Neurotransmitters	1040	An Immunoglobulin's Constant Region Determines Its Functional Properties	1072
A Calcium-Binding Protein Regulates Fusion of Synaptic Vesicles with the Plasma Membrane	1041	23.3 Generation of Antibody Diversity and B-Cell Development	1073
Fly Mutants Lacking Dynamin Cannot Recycle Synaptic Vesicles	1042	A Functional Light-Chain Gene Requires Assembly of V and J Gene Segments	1074
Signaling at Synapses Is Terminated by Degradation or Reuptake of Neurotransmitters	1042	Rearrangement of the Heavy-Chain Locus Involves V, D, and J Gene Segments	1075
Opening of Acetylcholine-Gated Cation Channels Leads to Muscle Contraction	1043	Somatic Hypermutation Allows the Generation and Selection of Antibodies with Improved Affinities	1077
All Five Subunits in the Nicotinic Acetylcholine Receptor Contribute to the Ion Channel	1044	B-Cell Development Requires Input from a Pre-B-Cell Receptor	1077
Nerve Cells Make an All-or-None Decision to Generate an Action Potential	1045	During an Adaptive Response, B Cells Switch from Making Membrane-Bound Ig to Making Secreted Ig	1079

Molecules, Cells, and Evolution

Nothing in biology makes sense except in the light of evolution.

—Theodosius Dobzhansky
(essay in *The American Biology Teacher* 35: 125–129, 1973)

Biology is a science fundamentally different from physics or chemistry, which deal with unchanging properties of matter that can be described by mathematical equations. Biological systems of course follow the rules of chemistry and physics, but biology is a historical science, as the forms and structures of the living world today are the results of billions of years of *evolution*. Through evolution, all organisms are related in a family tree extending from primitive single-celled organisms that lived in the distant past to the diverse plants, animals, and microorganisms of the present era (Figure 1-1, Table 1-1). The great insight of Charles Darwin (Figure 1-2) was the principle of natural selection: organisms vary randomly and compete within their environment for resources. Only those that survive to reproduce are able to pass down their genetic traits.

At first glance, the biological universe appears amazingly diverse—from tiny ferns to tall fir trees, from single-celled

bacteria and protozoans visible only under a microscope to multicellular animals of all kinds. Yet the bewildering array of outward biological forms overlies a powerful uniformity: thanks to our common ancestry, all biological systems are composed of the same types of chemical molecules and employ similar principles of organization at the cellular level. Although the basic kinds of biological molecules have been conserved during the billions of years of evolution, the patterns in which they are assembled to form functioning cells and organisms have undergone considerable change.

We now know that **genes**, which chemically are composed of **deoxyribonucleic acid (DNA)**, ultimately define biological structure and maintain the integration of cellular function. Many genes encode **proteins**, the primary molecules that make up cell structures and carry out cellular activities. Alterations in the structure and organization of genes, or **mutations**, provide the random variation that can alter biological structure and function. While the vast majority of random mutations have no observable effect on a gene's or protein's function, many are deleterious, and only a few confer an evolutionary advantage. In all organisms mutations in DNA are constantly occurring, allowing over time the small alterations

OUTLINE

- 1.1 The Molecules of Life** 4
- 1.2 Genomes, Cell Architecture, and Cell Function** 10

- 1.3 Cells into Tissues: Unicellular and Metazoan Organisms Used for Molecular Cell Biology Investigations** 16

FIGURE 1-1 All living organisms descended from a common ancestral cell. (a) All organisms from simple bacteria to complex mammals probably evolved from a common single-celled ancestor. This family tree depicts the evolutionary relations among the three major lineages of organisms. The structure of the tree was initially ascertained from morphological criteria: creatures that look alike were put close together. More recently the sequences of DNA and proteins found in organisms have been examined as more information-rich criteria for assigning relationships. The greater the similarities in these macromolecular sequences, the more closely related organisms are thought to be. The trees based on morphological comparisons and the

fossil record generally agree well with those based on molecular data. (b) Evolution of great apes, a small ape, and an Old World monkey with respect to humans, as estimated from the divergence among their genomic DNA sequences. Whole genome DNA sequences were aligned, and the average nucleotide divergence in unique DNA sequences was estimated. Estimates of the times different species diverged from each other, calculated in millions of years (Myr), are indicated at each node; ~1 Myr implies approximately 1 Myr or less. [Part (a) adapted from J. R. Brown, 2005, "Universal tree of life," in *Encyclopedia of Life Sciences*, Wiley InterScience (online). Part (b) adapted from D. P. Locke et al., 2011, *Nature* 469:529.]

TABLE 1-1 Timeline for Evolution of Life on Earth, as Determined from the Fossil Record

4600 million years ago	The planet Earth forms from material revolving around the young Sun.
~3900–2500 million years ago	Cells resembling prokaryotes appear. These first organisms are chemoautotrophs: they use carbon dioxide as a carbon source and oxidize inorganic materials to extract energy.
3500 million years ago	Lifetime of the last universal ancestor; the split between bacteria and archaea occurs.
2700 million years ago	Photosynthesizing cyanobacteria evolve; they use water as a reducing agent, thereby producing oxygen as a waste product.
1850 million years ago	Unicellular eukaryotic cells appear.
1200 million years ago	Simple multicellular organisms evolve, mostly consisting of cell colonies of limited complexity.
580–500 million years ago	Most modern phyla of animals begin to appear in the fossil record during the Cambrian explosion.
535 million years ago	Major diversification of living things in the oceans: chordates, arthropods (e.g., trilobites, crustaceans), echinoderms, mollusks, brachiopods, foraminifers, radiolarians, etc.
485 million years ago	First vertebrates with true bones (jawless fishes) evolve.
434 million years ago	First primitive plants arise on land.
225 million years ago	Earliest dinosaurs (prosauropods) and teleost fishes appear.
220 million years ago	Gymnosperm forests dominate the land; herbivores grow to huge sizes.
215 million years ago	First mammals evolve.
65.5 million years ago	The Cretaceous-Tertiary extinction event eradicates about half of all animal species, including all of the dinosaurs.
6.5 million years ago	First hominids evolve.
2 million years ago	First members of the genus <i>Homo</i> appear.
350 thousand years ago	Neanderthals appear.
200 thousand years ago	Anatomically modern humans appear in Africa.
30 thousand years ago	Extinction of Neanderthals.

in cellular structures and functions that may prove to be advantageous. Entirely new structures rarely are created; more often, old structures are adapted to new circumstances. More rapid change is possible by rearranging or multiplying previously evolved components rather than by waiting for a wholly new approach to emerge. For instance, in a particular organism one gene may randomly become duplicated; one copy of the gene and its encoded protein may retain their original function while over time the second copy of the gene mutates such that its protein takes on a slightly different or even a totally new function. The cellular organization of

organisms plays a fundamental role in this process because it allows these changes to come about by small alterations in previously evolved cells, giving them new abilities. The result is that closely related organisms have very similar genes, proteins, and cellular organization.

Living systems, including the human body, consist of such closely interrelated elements that no single element can be fully appreciated in isolation from the others. Organisms contain organs, organs are composed of tissues, tissues consist of cells, and cells are formed from molecules (Figure 1-3). The unity of living systems is coordinated by many levels of

FIGURE 1-2 Charles Darwin (1809–1882). Four years after his epic voyage on HMS Beagle, Darwin had already begun formulating in private notebooks his concept of natural selection, which would be published in *Origin of Species* (1859). [Walt Anderson/Visuals Unlimited, Inc.]

interrelationship: molecules carry messages from organ to organ and cell to cell and tissues are delineated and integrated with other tissues by molecules secreted by cells. Generally all the levels into which we fragment biological systems interconnect.

To learn about biological systems, however, we must examine one small portion of a living system at a time. The biology of cells is a logical starting point because an organism can be viewed as consisting of interacting cells, which are the closest thing to an autonomous biological unit that exists. The last common ancestor of all life on earth was a cell, and at the cellular level all life is remarkably similar. All cells use the same molecular building blocks, similar methods for the storage, maintenance, and expression of genetic information, and similar processes of energy metabolism, molecular transport, signaling, development, and structure.

In this chapter, we introduce the common features of cells. We begin with a brief discussion of the principal small molecules and macromolecules found in biological systems. Next we discuss the fundamental aspects of cell structure and function that are conserved in present-day organisms, and the use of prokaryotic organisms (single-celled organisms without a nucleus) to study the basic molecules of life.

In the third section we discuss the formation of tissues from individual cells, and the diverse types of unicellular and multicellular organisms used in investigations of molecular cell biology.

One focus of this chapter is DNA, as we now have the complete sequence of the genomes of over a hundred organisms and these have provided considerable insight into the evolution of genes and organisms. Recent studies, for instance, indicate that human and chimpanzee genomes are about 99 percent identical in sequence and that the ancestors of these species likely diverged from a common ape-like organism between 4.5 and 6 million years ago (see Figure 1-1b). This conclusion is consistent with the fossil record (see Table 1-1). Biologists use evolution as a research tool: if a gene and its protein have been conserved in, say, all **metazoans** (multicellular animals) but are not found in unicellular organisms, the protein likely has an important function in all metazoans and thus can be studied in whatever metazoan organism is most suitable for the investigation. Interwoven in the second and third sections of this chapter are discussions of the reasons scientists pick particular unicellular and multicellular “model” organisms to study specific genes and proteins that are important for cellular function.

1.1 The Molecules of Life

While large polymers are the focus of molecular cell biology, small molecules are the stage upon which all cellular processes are set. Water, inorganic ions, and a wide array of relatively small organic molecules (Figure 1-4) account for 75 to 80 percent of living matter by weight, and water accounts for about 75 percent of a cell’s volume. These small molecules, including water, serve as substrates for many of the reactions that take place inside the cell, including energy metabolism and cell signaling. Cells acquire these small molecules in different ways. Ions, water, and many small organic molecules are imported into the cell (Chapter 11); other small molecules are synthesized within the cell, often by a series of chemical reactions.

Even in the structures of many small molecules, such as sugars, vitamins, and amino acids, we see the footprint of evolution. For example, all amino acids save glycine have an asymmetric carbon atom, yet only the L-stereoisomer, never the D-stereoisomer, is incorporated into proteins. Similarly, only the D-stereoisomer of glucose is invariably found in cells, never the mirror image L-stereoisomer (see Figure 1-4). At an early stage of biological evolution, our common cellular ancestor evolved the ability to catalyze reactions with one stereoisomer instead of the other. How these selections happened is unknown, but now these choices are locked in place.

An important and universally conserved small molecule is **adenosine triphosphate (ATP)**, which stores readily available chemical energy in two of its chemical bonds (Figure 1-5). When one of these energy-rich bonds in ATP is broken, forming **ADP (adenosine diphosphate)**, the released

FIGURE 1-3 Living systems such as the human body consist of closely interrelated elements. (a) The surface of our hand is covered by a living organ, skin, that is comprised of several layers of tissue. (b) An outer covering of hard, dead skin cells protects the body from injury, infection, and dehydration. This layer is constantly renewed by living epidermal cells, which also give rise to hair and fur in animals. Deeper layers of muscle and connective tissue give skin its tone and firmness.

(c) Tissues are formed through subcellular adhesion structures (desmosomes and hemidesmosomes) that join cells to each other and to an underlying layer of supporting fibers. (d) At the heart of cellular adhesion are its structural components: phospholipid molecules that make up the cell surface membrane, and large protein molecules. Protein molecules that traverse the cell membrane often form strong bonds with internal and external fibers made of multiple proteins.

FIGURE 1-4 Some of the many small molecules found in cells. Only the L-forms of amino acids such as serine are incorporated into proteins, not their D-mirror images; only the D-form of glucose, not its L-mirror image, can be metabolized to carbon dioxide and water.

energy can be harnessed to power an energy-requiring process such as muscle contraction or protein biosynthesis. To obtain energy for making ATP, all cells break down food molecules. For instance, when sugar is degraded to carbon dioxide and water, the energy stored in the sugar molecule's chemical bonds is released and much of it can be "captured" in the energy-rich bonds in ATP (Chapter 12). Bacterial, plant, and animal cells can all make ATP by this process. In addition, plants and a few other organisms can harvest energy from sunlight to form ATP in **photosynthesis**.

Other small molecules (e.g., hormones and growth factors) act as signals that direct the activities of cells (Chapters 15 and 16), and nerve cells communicate with one another by releasing and sensing certain small signaling molecules (Chapter 22). The powerful effect on our body of a frightening event comes from the instantaneous flooding of the body with the small-molecule hormone adrenaline, which mobilizes the "fight or flight" response.

Certain small molecules (**monomers**) can be joined to form **polymers**, also called **macromolecules**, through repetition of a

FIGURE 1-5 Adenosine triphosphate (ATP) is the most common molecule used by cells to capture and transfer energy. ATP is formed from adenosine diphosphate (ADP) and inorganic phosphate

(P_i) by photosynthesis in plants, and by the breakdown of sugars and fats in most cells. The energy released by the splitting (hydrolysis) of P_i from ATP drives many cellular processes.

single type of covalent chemical-linkage reaction (see Figure 2-1). Cells produce three types of large macromolecules: polysaccharides, proteins, and nucleic acids (Figure 1-6). Sugars, for example, are the monomers used to form polysaccharides. Different polymers of D-glucose form the cellulose component of plant cell walls and glycogen, a storage form of glucose found in liver and muscle. The cell is careful to provide the appropriate mix of small molecules needed as precursors for synthesis of macromolecules.

Proteins Give Cells Structure and Perform Most Cellular Tasks

Proteins, the workhorses of the cell, are the most abundant and functionally versatile of the cellular macromolecules. Cells string together 20 different **amino acids** in a linear chain to form proteins (see Figure 2-14), which commonly range in length from 100 to 1000 amino acids. During its polymerization a linear chain of amino acids folds into a complex shape, conferring a distinctive three-dimensional structure and function on each protein (see Figure 1-6). Humans obtain amino acids either by synthesizing them from other molecules or by breaking down proteins that we eat.

Proteins have a variety of functions in the cell. Many proteins are **enzymes**, which accelerate (catalyze) chemical reactions involving small molecules or macromolecules (Chapter 3). Certain proteins catalyze steps in the synthesis of proteins; others catalyze synthesis of other macromolecules

such as DNA and RNA. **Cytoskeletal proteins** serve as structural components of a cell, for example by forming an internal skeleton; others power the movement of subcellular structures such as chromosomes, and even of whole cells, by using energy stored in the chemical bonds of ATP (Chapters 17 and 18). Other proteins bind adjacent cells together or form parts of the extracellular matrix (see Figure 1-3). Proteins can be sensors that change shape as temperature, ion concentrations, or other properties of the cell change. Many proteins that are embedded in the cell surface (plasma) membrane import and export a variety of small molecules and ions (Chapter 11). Some proteins, such as insulin, are hormones; others are hormone receptors that bind their target proteins and then generate a signal that regulates a specific aspect of cell function. Other important classes of proteins bind to specific segments of DNA, turning genes on or off (Chapter 7). In fact, much of molecular cell biology consists of studying the function of specific proteins in specific cell types.

How can 20 amino acids form all the different proteins needed to perform these varied tasks? It seems impossible at first glance. But if a “typical” protein is about 400 amino acids long, there are 20⁴⁰⁰ possible different amino acid sequences. Even assuming that many of these would be functionally equivalent, unstable, or otherwise discountable, the number of possible proteins is astronomical.

Next we might ask how many protein molecules a cell needs to operate and maintain itself. To estimate this number,

FIGURE 1-6 Models of some representative proteins drawn to a common scale and compared with a small portion of a lipid bilayer sheet, a DNA molecule, and an RNA molecule. Each protein has a defined three-dimensional shape held together by numerous chemical

bonds. The illustrated proteins include enzymes (glutamine synthetase and adenylate kinase), an antibody (immunoglobulin), a hormone (insulin), and the blood's oxygen carrier (hemoglobin).

let's take a typical eukaryotic cell (a cell containing a nucleus), such as a hepatocyte (liver cell). This cell, roughly a cube $15\ \mu\text{m}$ ($0.0015\ \text{cm}$) on a side, has a volume of $3.4 \times 10^{-9}\ \text{cm}^3$ (or milliliters, ml). Assuming a cell density of $1.03\ \text{g/ml}$, the cell would weigh $3.5 \times 10^{-9}\ \text{g}$. Since protein accounts for approximately 20 percent of a cell's weight, the total weight of cellular protein is $7 \times 10^{-10}\ \text{g}$. The average protein has a molecular weight of $52,700\ \text{g/mol}$; we can calculate the total number of protein molecules per liver cell as about 7.9×10^9 from the total protein weight and Avogadro's number, the number of molecules per mole of any chemical compound (6.02×10^{23}). To carry this calculation one step further, consider that a liver cell contains about 10,000 different proteins; thus each cell would on average contain close to a million molecules of each type of protein. In fact, the abundance of different proteins varies widely, from the quite rare insulin-binding receptor protein (20,000 molecules per cell) to the abundant structural protein actin (5×10^8 molecules per cell). Every cell closely regulates the level of each protein such that each is present in the appropriate quantity for its cellular functions, as we detail in Chapters 7 and 8.

Nucleic Acids Carry Coded Information for Making Proteins at the Right Time and Place

The macromolecule that garners the most public attention is deoxyribonucleic acid (DNA), whose functional properties make it the cell's "master molecule." The three-dimensional structure of DNA, first proposed by James D. Watson and Francis H. C. Crick about 60 years ago (Figure 1-7), consists of two long helical strands that are coiled around a common axis to form a double helix (Figure 1-8). The double-helical structure of DNA, one of nature's most magnificent constructions, is critical to the phenomenon of heredity, the

transfer of genetically determined characteristics from one generation to the next.

DNA strands are composed of monomers called **nucleotides**; these often are referred to as *bases* because their structures contain cyclic organic bases (Chapter 4). Four different

FIGURE 1-7 James D. Watson (left) and Francis H. C. Crick (right) with the double-helical model of DNA they constructed in 1952–1953. Their model ultimately proved correct in all its essential aspects. [A. Barrington Brown/Science Photo Researcher. From J. D. Watson, 1968, *The Double Helix*, Atheneum, Copyright 1968, p. 215; Courtesy of A. C. Barrington Brown.]

FIGURE 1-8 DNA consists of two complementary strands wound around each other to form a double helix. The double helix is stabilized by weak hydrogen bonds between the A and T bases and between the C and G bases. During replication, the two strands are unwound and used as templates to produce complementary strands. The outcome is two copies of the original double helix, each containing one of the original strands and one new daughter (complementary) strand.

nucleotides, abbreviated A, T, C, and G, are joined to form a DNA strand, with the base parts projecting inward from the backbone of the strand. Two strands bind together via the bases, and twist to form a double helix. Each DNA double

helix has a simple construction: wherever one strand has an A, the other strand has a T, and each C is matched with a G (see Figure 1-8). This **complementary** matching of the two strands is so strong that if complementary strands are separated, they

TABLE 1-2 Genome Sizes of Organisms Used in Molecular Cell Biology Research That Have Been Completely Sequenced

Bacteria	Base pairs (millions)	Encoded proteins	Chromosomes	Reference

will spontaneously zip back together under the right salt concentration and temperature conditions. Such **nucleic acid hybridization** is extremely useful for detecting one strand by using the other, as we learn in Chapter 5.

The genetic information carried by DNA resides in its sequence, the linear order of nucleotides along a strand. Specific segments of DNA, termed **genes**, carry instructions for making specific proteins. Commonly genes contain two parts: the *coding region* specifies the amino acid sequence of a protein; the *regulatory region* binds specific proteins and controls when and in which cells the protein is made.

Most bacteria have a few thousand genes; yeasts and other unicellular eukaryotes have about 5000. Humans and other metazoans have between 13,000 and 23,000, while many plants like *Arabidopsis* have more (Table 1-2). As we discuss later in this chapter, many bacterial genes encode proteins that are conserved throughout all living organisms. These catalyze reactions that occur universally, such as the metabolism of glucose and synthesis of nucleic acids and proteins. Studies on bacterial cells have yielded profound insights into these basic life processes. Similarly, many genes in unicellular eukaryotes such as yeasts encode proteins that are conserved throughout all eukaryotes; we will see how yeasts have been used to study processes such as cell division that have yielded profound insights into human diseases such as cancer.

Cells use two processes in series to convert the coded information in DNA into proteins (Figure 1-9). In the first, called **transcription**, the coding region of a gene is copied into a single-stranded ribonucleic acid (RNA) whose sequence is the same as one of the two in the double-stranded DNA. A large enzyme, **RNA polymerase**, catalyzes the linkage of nucleotides into an RNA chain using DNA as a template. In eukaryotic cells, the initial RNA product is processed into a smaller **messenger RNA (mRNA)** molecule, which moves out of the nucleus to the cytoplasm. Here the **ribosome**, an enormously complex molecular machine composed of both RNA and protein, carries out the second process, called **translation**. During translation, the ribosome assembles and links together amino acids in the precise order dictated by the mRNA sequence according to the nearly universal **genetic code**. We examine the cell components that carry out transcription and translation in detail in Chapter 4.

In addition to its role in transferring information from nucleus to cytoplasm, RNA can serve as a framework for building a molecular machine. For example, the ribosome is built of four RNA chains that bind to more than 50 proteins to make a remarkably precise and efficient mRNA reader and protein synthesizer. While most chemical reactions in cells are catalyzed by proteins, a few, such as the formation of the peptide bonds that connect amino acids in proteins, are catalyzed by RNA molecules.

Well before the entire human genome was sequenced it was apparent that only about 5 percent of human DNA codes for protein, and for many years most of the human genome was considered “junk DNA”! However, in recent years we’ve learned that much of the so-called junk DNA is actually copied into thousands of RNA molecules that,

FIGURE 1-9 The information coded in DNA is converted into the amino acid sequences of proteins by a multistep process. Step **1**: Transcription factors bind to the regulatory regions of the specific genes they control and activate them. Step **2**: Following assembly of a multiprotein initiation complex bound to the DNA, RNA polymerase begins transcription of an activated gene at a specific location, the start site. The polymerase moves along the DNA linking nucleotides into a single-stranded pre-mRNA transcript using one of the DNA strands as a template. Step **3**: The transcript is processed to remove noncoding sequences. Step **4**: In a eukaryotic cell, the mature messenger RNA (mRNA) moves to the cytoplasm, where it is bound by ribosomes that read its sequence and assemble a protein by chemically linking amino acids into a linear chain.

though they do not code for proteins, serve equally important purposes in the cell (Chapter 6). Small *micro RNAs*, 20–25 nucleotides long, are abundant in metazoan cells and bind to and repress the activity of target mRNAs. By some estimates these small RNAs may indirectly regulate the activity of most or all genes, though the mechanisms and ubiquity of this type of regulation are still being explored (Chapter 8). Several long noncoding RNAs bind to DNA or chromosomal proteins and so affect chromosome structure and RNA synthesis, processing, and stability. However, we know the function of only very few of these abundant noncoding RNAs.

All organisms must control when and where their genes can be transcribed. Nearly all the cells in our bodies contain the full set of human genes, but in each cell type only some of these genes are active, or turned on, and used to make

proteins. For instance, liver cells produce some proteins that are not produced by kidney cells, and vice versa. Moreover, many cells respond to external signals or changes in external conditions by turning specific genes on or off, thereby adapting their repertoire of proteins to meet current needs. Such control of gene activity depends on DNA-binding proteins called **transcription factors**, which bind to specific sequences of DNA and act as switches, either activating or repressing transcription of particular genes (see Figure 1-9 and Chapter 7). Transcription factors often work as multiprotein complexes, with each protein contributing its own DNA-binding specificity to selecting the regulated genes.

Phospholipids Are the Conserved Building Blocks of All Cellular Membranes

In essence, any cell is simply a compartment with a watery interior that is separated from the external environment by a surface membrane, the plasma membrane, which prevents the free flow of molecules in and out. In addition, eukaryotic cells have extensive internal membranes that further subdivide the cell into multiple subcompartments, the organelles.

In all organisms cellular membranes are composed primarily of a bilayer (two layers) of phospholipid molecules. These bipartite molecules have a “water-loving” (hydrophilic) end and a “water-hating” (hydrophobic) end. The two phospholipid layers of a membrane are oriented with all the hydrophilic ends directed toward the inner and outer surfaces of the membrane and the hydrophobic ends buried within its interior (Figure 1-10). Smaller amounts of other lipids, such as cholesterol, are inserted into the phospholipid framework. Phospholipid membranes are impermeable to water, all ions, and virtually all hydrophilic small molecules. Thus each

membrane in each cell also contains groups of proteins that allow specific ions and small molecules to cross. Other membrane proteins serve to attach the cell to other cells or to polymers that surround it; still others give the cell its shape or allow its shape to change. We will learn more about membranes and how molecules cross them in Chapters 10 and 11.

New cells are always derived from parental cells by cell division. We’ve seen that the synthesis of new DNA molecules is templated by the two strands of the parental DNA such that each daughter DNA molecule has the same sequence as the parental one. In parallel, membranes are made by incorporation of lipids and proteins into existing membranes in the parental cell, and these are divided between daughter cells by fission. Thus membrane synthesis, similarly to DNA synthesis, is also templated by a parental structure.

1.2 Genomes, Cell Architecture, and Cell Function

The biological universe consists of two types of cells—prokaryotic and eukaryotic. Prokaryotic cells such as bacteria consist of a single closed compartment that is surrounded by the plasma membrane, lack a defined nucleus, and have a relatively simple internal organization (Figure 1-11). Eukaryotic cells, unlike prokaryotic cells, contain a defined membrane-bound nucleus and extensive internal membranes that enclose the **organelles** (Figure 1-12). The region of the cell lying between the plasma membrane and the nucleus is the **cytoplasm**, comprising the **cytosol** (water, dissolved ions, small molecules, and proteins) and the organelles. Eukaryotes include four kingdoms: the plants, animals, fungi, and protists. Prokaryotes comprise the fifth and sixth kingdoms: the eubacteria (true bacteria) and archaea.

Genome sequencing has provided profound insights into the function and evolution of both conserved and nonconserved genes and proteins found in multiple organisms. In the following section we describe some basic structural and functional features of prokaryotic and eukaryotic cells and relate these to insights provided from their genome sequences. We emphasize the conserved proteins found in multiple diverse species and explain why scientists have chosen several of these species as **model organisms**, systems in which the study of specific aspects of cellular function and development can serve as a model for other species (Figure 1-13).

Prokaryotes Comprise True Bacteria and Archaea

In recent years, detailed analysis of the DNA sequences from a variety of prokaryotic organisms has revealed two distinct kingdoms: the eubacteria, often simply called “bacteria,” and the archaea. Eubacteria, a numerous type of prokaryote, are single-celled organisms; included are the cyanobacteria, or blue-green algae, which can be unicellular or filamentous chains of cells. Figure 1-11 illustrates the general structure of a typical bacterial cell; archaeal cells have a similar structure.

FIGURE 1-10 The watery interior of cells is surrounded by the plasma membrane, a two-layered shell of phospholipids. The phospholipid molecules are oriented with their hydrophobic fatty acyl chains (black squiggly lines) facing inward and their hydrophilic head groups (white spheres) facing outward. Thus both sides of the membrane are lined by head groups, mainly charged phosphates, adjacent to the watery spaces inside and outside the cell. All biological membranes have the same basic phospholipid bilayer structure. Cholesterol (red) and various proteins are embedded in the bilayer. The interior space is actually much larger relative to the volume of the plasma membrane than is depicted here.

FIGURE 1-11 Prokaryotic cells have a relatively simple structure. (Left) Electron micrograph of a thin section of *Escherichia coli*, a common intestinal bacterium. The nucleoid, consisting of the bacterial DNA, is not enclosed within a membrane. *E. coli* and other gram-negative bacteria are surrounded by two membranes separated by the periplasmic space. The thin cell wall is adjacent to the inner

membrane. (Right) This artist's drawing shows the nucleoid (blue) and a magnification of the layers that surround the cytoplasm. Most of the cell is composed of water, proteins, ions, and other molecules that are too small to be depicted in the scale of this drawing. [Electron micrograph courtesy of I. D. J. Burdett and R. G. E. Murray. Illustration by D. Goodsell.]

Bacterial cells are commonly 1–2 μm in size and consist of a single closed compartment containing the cytoplasm and bounded by the plasma membrane. Although bacterial cells do not have a defined nucleus, the single circular DNA genome is extensively folded and condensed into the central region of the cell. In contrast, most ribosomes are found in the DNA-free region of the cell. Some bacteria also have an invagination of the cell membrane, called a *mesosome*, which is associated with synthesis of DNA and secretion of

proteins. Many proteins are precisely localized within the cytosol or in the plasma membrane, indicating the presence of an elaborate internal organization.

Bacterial cells possess a cell wall, which lies adjacent to the external side of the plasma membrane. The cell wall is composed of layers of peptidoglycan, a complex of proteins and oligosaccharides; it helps protect the cell and maintain its shape. Some bacteria (e.g., *E. coli*) have a thin inner cell wall and an outer membrane separated from the inner cell

FIGURE 1-12 Eukaryotic cells have a complex internal structure with many membrane-limited organelles. (a) Electron micrograph and (b) diagram of a plasma cell, a type of white blood cell that secretes antibodies. A single membrane (the plasma membrane) surrounds the cell and the cell interior contains many membrane-limited compartments, or organelles. The defining characteristic of eukaryotic cells is segregation of the cellular DNA within a defined nucleus, which is bounded by a double membrane. The outer nuclear membrane is

continuous with the rough endoplasmic reticulum, a factory for assembling secreted and membrane proteins. Golgi vesicles process and modify secreted and membrane proteins, mitochondria generate energy, lysosomes digest cell materials to recycle them, peroxisomes process molecules using oxygen, and secretory vesicles carry cell materials to the surface to release them. [From P. C. Cross and K. L. Mercer, 1993, *Cell and Tissue Ultrastructure: A Functional Perspective*, W. H. Freeman and Company.]

FIGURE 1-13 Each experimental organism used in cell biology has advantages for certain types of studies. Viruses (a) and bacteria (b) have small genomes amenable to genetic dissection. Many insights into gene control initially came from studies with these organisms. The yeast *Saccharomyces cerevisiae* (c) has the cellular organization of a eukaryote but is a relatively simple single-celled organism that is easy to grow and to manipulate genetically. In the nematode worm *Caenorhabditis elegans* (d), which has a small number of cells arranged in a nearly identical way in every worm, the formation of each individual cell can be traced. The fruit fly *Drosophila melanogaster* (e), first used to discover the properties of chromosomes, has been especially valuable in identifying genes that control embryonic development. Many of these genes are evolutionarily conserved in humans. The zebrafish *Danio rerio* (f) is used for rapid genetic screens to identify genes that control vertebrate development and organogenesis. Of the experimental animal systems, mice (*Mus*

musculus) (g) are evolutionarily the closest to humans and have provided models for studying numerous human genetic and infectious diseases. The mustard-family weed *Arabidopsis thaliana* has been used for genetic screens to identify genes involved in nearly every aspect of plant life. Genome sequencing is completed for many viruses and bacterial species, the yeast *S. cerevisiae*, the roundworm *C. elegans*, the fruit fly *D. melanogaster*, humans, mice, zebrafish, and the plant *A. thaliana*. Other organisms, particularly frogs, sea urchins, chickens, and slime molds, have also had their genomes sequenced and continue to be immensely valuable for cell biology research. Increasingly, a wide variety of other species are used, especially for studies of evolution of cells and mechanisms. [Part (a) Visuals Unlimited, Inc. Part (b) Kari Lountmaa/Science Photo Library/Photo Researchers, Inc. Part (c) Scimat/Photo Researchers, Inc. Part (d) Photo Researchers, Inc. Part (e) Darwin Dale/Photo Researchers, Inc. wall by the periplasmic space. Such bacteria are not stained by the Gram technique and thus are classified as gram-negative. Other bacteria (e.g., *Bacillus polymyxa*) that have a thicker cell wall and no outer membrane take the Gram stain and thus are classified as gram-positive.

Working on the assumption that similar organisms diverged more recently from a common ancestor than did dissimilar ones, researchers have developed the evolutionary lineage tree shown in Figure 1-1a. According to this tree, the archaea and the eukaryotes diverged from bacteria more than a billion years before they diverged from each other (Table 1-1). In addition to DNA sequence distinctions that define the three groups of organisms, archaeal cell membranes have chemical properties that differ dramatically from those of bacteria and eukaryotes.

Many archaeans grow in unusual, often extreme, environments that may resemble the ancient conditions that existed when life first appeared on earth. For instance, halophiles ("salt lovers") require high concentrations of salt to survive, and thermoacidophiles ("heat and acid lovers") grow in hot (80 °C) sulfur springs, where a pH of less than 2 is common. Still other archaeans live in oxygen-free milieus and generate methane (CH₄) by combining water with carbon dioxide.

***Escherichia coli* Is Widely Used in Biological Research**

The bacterial lineage includes *Escherichia coli*, a favorite experimental organism which in nature is common in soil and animal intestines. *E. coli* and several other bacteria have a number of advantages as experimental organisms. They grow rapidly in a simple and inexpensive medium containing glucose and salts, in which they can synthesize all necessary amino acids, lipids, vitamins, and other essential small molecules. Like all bacteria, *E. coli* possesses elegant mechanisms for controlling gene activity that are now well understood. Over time, workers have developed powerful systems for genetic analysis of this organism. These systems are facilitated by the small size of bacterial genomes, the ease of obtaining mutants, the availability of techniques for transferring genes into bacteria, an enormous wealth of knowledge about bacterial gene control and protein functions, and the relative simplicity of mapping genes relative to one another in the bacterial genome. In Chapter 5 we see how *E. coli* is used in recombinant DNA research.

Bacteria such as *E. coli* that grow in environments as diverse as the soil and the human gut have about 4000 genes encoding about the same number of proteins (see Table 1-2). Parasitic bacteria such as the *Mycoplasma* species acquire amino acids and other nutrients from their host cells, and lack the genes for enzymes that catalyze reactions in the synthesis of amino acids and certain lipids. Many bacterial genes encoding proteins essential for DNA, RNA, protein synthesis, and membrane function are conserved in all organisms, and much of our knowledge of these important cellular processes was uncovered first in *E. coli*. For example, certain *E. coli* cell membrane proteins that import amino acids across the plasma membrane are closely related in sequence, structure,

and function to membrane proteins in certain mammalian brain cells that import small nerve-to-nerve signaling molecules called neurotransmitters (Chapters 11 and 22).

All Eukaryotic Cells Have Many of the Same Organelles and Other Subcellular Structures

Eukaryotes comprise all members of the plant and animal kingdoms, as well as fungi (e.g., yeasts, mushrooms, molds) and protozoans (*proto*, primitive; *zoan*, animal), which are exclusively unicellular. Eukaryotic cells are commonly about 10–100 μm across, generally much larger than bacteria. A typical human fibroblast, a connective tissue cell, is about 15 μm across with a volume and dry weight some thousands of times those of an *E. coli* cell. An amoeba, a single-celled protozoan, can have a cell diameter of approximately 0.5 mm, more than thirty times that of a fibroblast.

Eukaryotic cells, like prokaryotic cells, are surrounded by a plasma membrane. However, unlike prokaryotic cells, most eukaryotic cells (the human red blood cell is an exception) also contain extensive internal membranes that enclose specific subcellular compartments, the **organelles**, and separate them from the rest of the **cytoplasm**, the region of the cell lying outside the nucleus (see Figure 1-12). Many organelles are surrounded by a single phospholipid membrane, but the nucleus, mitochondrion, and chloroplast are enclosed by two membranes. Each type of organelle contains a collection of specific proteins, including enzymes that catalyze requisite chemical reactions. The membranes defining these subcellular compartments control their internal ionic composition so that it generally differs from that of the surrounding cytosol as well as that of the other organelles.

The largest organelle in a eukaryotic cell is generally the nucleus, which houses most of the cellular DNA. In animal and plant cells, most ATP is produced by large multiprotein "molecular machines" located in the organelles termed **mitochondria**. Plants carry out photosynthesis in **chloroplasts**, organelles that contain molecular machines for synthesizing ATP from ADP and phosphate, similar to those found in mitochondria. Similar molecular machines for generating ATP are located in the plasma membrane of bacterial cells. Both mitochondria and chloroplasts are thought to have originated as bacteria that took up residence inside eukaryotic cells and then became welcome collaborators (Chapter 12). Over time many of the bacterial genes "migrated" to the cell nucleus and became incorporated into the cell's nuclear genome. Both mitochondria and chloroplasts contain small genomes that encode a few of the essential organelle proteins; the sequences of these DNAs reveal their bacterial origins.

Cells need to break down worn-out or obsolete parts into small molecules that can be discarded or recycled. In animals this housekeeping task is assigned in part to **lysosomes**, organelles filled with degradative enzymes. The interior of a lysosome has a pH of about 5.0, much more acidic than that of the surrounding cytosol. This aids in the breakdown of materials by lysosomal enzymes, which can function at such a low pH. To create the low-pH environment,

FIGURE 1-14 The three types of cytoskeletal filaments have characteristic distributions within mammalian cells. Three views of the same cell. A cultured fibroblast was permeabilized and then treated with three different antibody preparations. Each antibody binds specifically to the protein monomers forming one type of filament and is chemically linked to a differently colored fluorescent dye (blue, red,

or green). Visualization of the stained cell in a fluorescence microscope reveals the location of filaments bound to a particular dye-antibody preparation. In this case, microtubules are stained blue; microfilaments, red; and intermediate filaments, green. All three fiber systems contribute to the shape and movements of cells. [Courtesy of V. Small.]

proteins located in the lysosomal membrane pump hydrogen ions into the lysosome using energy supplied from ATP (Chapter 11). Plants and fungi contain a vacuole that also has a low-pH interior and stores certain salts and nutrients. Peroxisomes are another type of small organelle, found in virtually all eukaryotic cells, that is specialized for breaking down the lipid components of membranes.

The cytoplasm of eukaryotic cells contains an array of fibrous proteins collectively called the **cytoskeleton** (Chapters 17 and 18). Three classes of fibers compose the cytoskeleton: **microtubules** (20 nm in diameter), built of polymers of the protein tubulin; **microfilaments** (7 nm in diameter), built of the protein actin; and **intermediate filaments** (10 nm in diameter), built of one or more rod-shaped protein subunits (Figure 1-14). The cytoskeleton gives the cell strength and rigidity, thereby helping to maintain cell shape. Cytoskeletal fibers also control movement of structures within the cell; for example, some cytoskeletal fibers connect to organelles or provide tracks along which organelles and chromosomes move; other fibers play key roles in cell motility. Thus the cytoskeleton is important for “organizing” the cell.

The rigid cell wall, composed of cellulose and other polymers, that surrounds plant cells contributes to their strength and rigidity. Fungi are also surrounded by a cell wall, but its composition differs from that of bacterial or plant cell walls.

Each organelle membrane and each space in the interior of an organelle has a unique set of proteins that enable it to carry out its specific functions. For cells to work properly, the numerous proteins composing the various working compartments must be transported from where they are made to their proper locations (Chapters 17 and 18). Some proteins are made on ribosomes that are free in the cytoplasm; from there, some proteins are moved into the nucleus while others are directed into mitochondria, chloroplasts, or peroxisomes, depending on their specific functions. Proteins to be secreted from the cell and most membrane proteins, in contrast, are made on ribosomes associated with the **endoplasmic reticulum (ER)**. This organelle produces, processes, and ships out both proteins and lipids. Most protein chains produced on the ER move to the **Golgi complex**, where they are further

FIGURE 1-15 Individual chromosomes can be seen in cells during cell division (mitosis). (a) During the S phase of the cell cycle (see Figure 1-16) chromosomes are duplicated and the daughter “sister chromatids,” each with a complete copy of the chromosomal DNA, remain attached at the centromere. (b) During the actual cell division process (mitosis) the chromosomal DNA becomes highly compacted and the pairs of sister chromatids can be seen in the electron microscope as depicted here. (c) Light microscopic image of a chromosomal spread from a cultured human male lymphoid cell arrested in the metaphase stage of mitosis by treatment with the microtubule-depolymerizing drug colcemid. There is a single copy of the duplicated X and Y chromosomes and two of each of the others. [Part (b) courtesy of Medical RF/The Medical File/Peter Arnold Inc. Part (c) courtesy of Tatyana Pyntikova.]

modified before being forwarded to their final destinations. Proteins that travel in this way contain short sequences of amino acids or attached sugar chains (oligosaccharides) that serve as addresses for directing them to their correct destinations. These addresses work because they are recognized and bound by other proteins that do the sorting and shipping in various cell compartments.

Cellular DNA Is Packaged Within Chromosomes

In most prokaryotic cells, most or all of the genetic information resides in a single circular DNA molecule about a millimeter in length; this molecule lies, folded back on itself many times, in the central region of the micrometer-sized cell (Figure 1-11). In contrast, DNA in the nuclei of eukaryotic cells is distributed among multiple long linear structures called **chromosomes**. The length and number of chromosomes are the same in all cells of an organism, but vary among different types of organisms (see Table 1-2). Each chromosome comprises a single DNA molecule associated with numerous proteins, and the total DNA in the chromosomes of an organism is referred to as its **genome**. Chromosomes, which stain intensely with basic dyes, are visible in light and electron microscopes only during cell division, when the DNA becomes tightly compacted (Figure 1-15). Although the large genomic DNA molecule in prokaryotes is associated with proteins and often is referred to as a chromosome, the arrangement of DNA within a bacterial chromosome differs greatly from that within the chromosomes of eukaryotic cells.

All Eukaryotic Cells Utilize a Similar Cycle to Regulate Their Division

Unicellular eukaryotes, animals, and plants use essentially the same **cell cycle**, a series of events that prepares a cell to divide, and the actual division process, called **mitosis**. The eukaryotic cell cycle commonly is represented as four stages

(Figure 1-16). The chromosomes and the DNA they carry are duplicated during the **S (synthesis) phase**. The replicated chromosomes separate during the **M (mitotic) phase**, with each daughter cell getting a copy of each chromosome during cell division. The M and S phases are separated by two gap stages, the **G₁ phase** and the **G₂ phase**, during which mRNAs and proteins are made and the cell increases in size.

In single-celled organisms, both daughter cells often (though not always) resemble the parent cell. In multicellular organisms, when many types of cells divide the daughters look a lot like the parent cell—liver cells, for instance, divide to generate two liver cells with the same characteristics and functions as their parent, as do insulin-producing cells in the pancreas. In contrast, **stem cells** and certain other undifferentiated cells can generate multiple types of differentiated descendant cells; these cells often divide such that the two daughter cells are different. Such **asymmetric cell division** is critical to the generation of different cell types in the body (Chapter 21). Often one daughter resembles its parent in that it remains undifferentiated and retains its ability to give rise to multiple types of differentiated cells. The other daughter divides many times and each of the daughter cells differentiates into a specific type of cell.

Under optimal conditions some bacteria, such as *E. coli*, can divide to form two daughter cells once every 30 minutes. Most eukaryotic cells take considerably longer to grow and divide, though cell divisions in the early *Drosophila* embryo require only 7 minutes. Moreover, the cell cycle in eukaryotes normally is highly regulated (Chapter 19). This tight control prevents imbalanced, excessive growth of cells and tissues if essential nutrients or certain hormonal signals are lacking. Some highly specialized cells in adult animals, such as nerve cells and striated muscle cells, divide rarely if at all. However, an organism usually replaces worn out cells or makes more cells in response to a new need, as exemplified by the growth of muscle in response to exercise or damage.

OVERVIEW ANIMATION: Life Cycle of a Cell

FIGURE 1-16 During growth, all eukaryotic cells continually progress through the four stages of the cell cycle, generating new daughter cells. In proliferating human cells, the four phases of the cell cycle proceed successively, taking from 10–20 hours depending on cell type and developmental state. Yeasts divide much faster. During interphase, which consists of the G₁, S, and G₂ phases, the cell roughly doubles its mass. Replication of DNA during the S phase leaves the cell with four copies of each type of chromosome. In the mitotic (M) phase, the chromosomes are evenly partitioned into two daughter cells, and the cytoplasm divides roughly in half in most cases. Under certain conditions, such as starvation or when a tissue has reached its final size, cells will stop cycling and remain in a waiting state called G₀. Most cells in G₀ can reenter the cycle if conditions change.

Another example is the formation of additional red blood cells when a person ascends to a higher altitude and needs more capacity to capture oxygen. The fundamental defect in cancer is loss of the ability to control the growth and division of cells. In Chapter 24 we examine the molecular and cellular events that lead to inappropriate, uncontrolled proliferation of cells.

1.3 Cells into Tissues: Unicellular and Metazoan Organisms Used for Molecular Cell Biology Investigations

Our current understanding of the molecular functioning of cells largely rests on studies of just a few types of organisms, termed *model organisms*. Because of the evolutionary conservation of genes, proteins, organelles, cell types, and so forth, discoveries about biological structures and functions obtained with one experimental organism often apply to others. Thus researchers generally conduct studies with the organism that is most suitable for rapidly and completely answering the question being posed, knowing that the results obtained in one organism are likely to be broadly applicable.

As we have seen, bacteria are excellent models for studies of several cellular functions, but they lack the organelles found in eukaryotes. Unicellular eukaryotes such as yeasts are used to study many fundamental aspects of eukaryotic cell structure and function. Multicellular, or *metazoan*, models are required to study more complex tissue and organ systems and development. As we will see in this section, several eukaryotic model organisms are in wide use to understand these complex cell systems and mechanisms.

Single-Celled Eukaryotes Are Used to Study Fundamental Aspects of Eukaryotic Cell Structure and Function

One group of single-celled eukaryotes, the yeasts, has proven exceptionally useful in molecular and genetic analysis of eukaryotic cell formation and function. Yeasts and their multicellular cousins, the molds, which collectively constitute the fungi, have an important ecological role in breaking down plant and animal remains for reuse. They also make numerous antibiotics and are used in the manufacture of bread, beer, and wine.

The common yeast used to make bread and beer, *Saccharomyces cerevisiae*, appears frequently in this book because it has proven to be an extremely useful experimental organism. Homologs of many of the approximately 6000 different proteins expressed in an *S. cerevisiae* cell (Table 1-2) are found in most if not all eukaryotes and are important for cell division or for the functioning of individual eukaryotic organelles. Much of what we know of the proteins in the endoplasmic reticulum and Golgi apparatus that promote protein secretion was elucidated first in yeasts. Yeasts were also essential for the identification of many proteins that regulate the cell

FIGURE 1-17 The yeast *Saccharomyces cerevisiae* can grow as both haploids and diploids and can reproduce sexually and asexually. (a) Scanning electron micrograph of the budding yeast *Saccharomyces cerevisiae*. These cells grow by an unusual type of mitosis termed mitotic budding. One daughter nucleus remains in the “mother” cell; the other daughter nucleus is transported into the bud, which grows in size and soon is released as a new cell. After each bud cell breaks free, a scar is left at the budding site, so the number of previous buds on the mother cell can be counted. The orange-colored cells are bacteria. (b) Haploid yeast cells can have different mating types, called *a* and *α*; both types contain a single copy of each yeast chromosome, half the usual number, and grow by mitotic budding. Two haploid cells that differ in mating type, one *a* and one *α*, can fuse together to form an *a/α* diploid cell that contains two copies of each chromosome; diploid cells also multiply by mitotic budding. Under starvation conditions, diploid cells undergo meiosis, a special type of cell division, to form haploid ascospores. Rupture of an ascus releases four haploid spores, which can germinate into haploid *a* and *α* cells. These also can multiply asexually. [Part (a) M. Abbey/VisualsUnlimited, Inc.]

cycle and catalyze DNA replication and transcription. *S. cerevisiae* (Figure 1-17a) and other yeasts offer many advantages to molecular and cellular biologists:

- Vast numbers of yeast cells can be grown easily and cheaply in culture from a single cell; such cell clones all have the same genes and the same biochemical properties. Individual proteins or multiprotein complexes can be purified from large amounts of cells and then studied in detail.

- Yeast cells can grow by mitosis both as haploids (containing one copy of each chromosome) and as diploids (containing two copies of each chromosome); this makes isolating and characterizing mutations in genes encoding essential cell proteins relatively straightforward.

- Yeasts, like many organisms, have a sexual cycle that allows exchange of genes between cells. Under starvation conditions, diploid cells undergo meiosis, a special type of cell division, to form haploid daughter cells, which are of two types, a and α cells. Haploid cells can also grow by mitosis. If haploid a and α cells encounter each other they can fuse, forming an a/α diploid cell that contains two copies of each chromosome (Figure 1-17b).

With the use of a single species like *S. cerevisiae* as a model organism, results from studies carried out by tens of thousands of scientists worldwide, using multiple experimental techniques, can be combined to yield a deeper level of understanding of a single type of cell. As we will see many times in this book, conclusions based on studies of *S. cerevisiae* are often generally true for all eukaryotes and form the basis for exploring the evolution of more complex processes in multicellular animals and plants.

Mutations in Yeast Led to the Identification of Key Cell Cycle Proteins

Biochemical studies can tell us much about an individual protein, but they cannot prove that it is required for cell division or any other cell process. The importance of a protein is demonstrated most firmly if a mutation that prevents its synthesis or makes it nonfunctional adversely affects the process under study. A diploid organism generally carries two versions (alleles) of each gene, one derived from each parent. There are important exceptions, such as the genes on the X and Y chromosomes in males of some species, including our own.

In a classical genetics approach, scientists isolate and characterize mutants that lack the ability to do something a normal organism can do. Often large genetic “screens” are done to look for many different mutant individuals (e.g., fruit flies, yeast cells) that are unable to complete a certain process, such as cell division or muscle formation. Mutations usually are produced by treatment with a mutagen, a chemical or physical agent that promotes mutations in a largely random fashion. But how can we isolate and maintain mutant organisms or cells that are defective in some process, such as cell division, that is necessary for survival?

One way is to isolate organisms with a temperature-sensitive mutation. These mutants are able to grow at the permissive temperature, but not at another, usually higher temperature, the nonpermissive temperature. Normal cells can grow at either temperature. In most cases, a temperature-sensitive mutant produces an altered protein that works at the permissive temperature but unfolds and is nonfunctional at the nonpermissive temperature. Temperature-sensitive screens are most readily done with haploid organisms

like yeasts since there is only one copy of each gene, and a mutation in it will immediately have a consequence.

By analyzing the effects of numerous different temperature-sensitive mutations that altered division of haploid yeast cells, geneticists discovered most of the genes necessary for cell division without knowing anything, initially, about which proteins they encode or how these proteins participate in the process. The great power of genetics is to reveal the existence and relevance of proteins without prior knowledge of their biochemical identity or molecular function. Eventually these “mutation-defined” genes were isolated and replicated (cloned) with recombinant DNA techniques discussed in Chapter 5. With the isolated genes in hand, the encoded proteins could be produced in the test tube or in engineered bacteria or cultured cells. Then biochemists could investigate whether the proteins associate with other proteins or DNA or catalyze particular chemical reactions during cell division (Chapter 19).

Most of these yeast cell cycle genes are found in human cells as well, and the encoded proteins have similar amino acid sequences. Proteins from different organisms, but with similar amino acid sequences, are said to be **homologous**, and may have the same or similar functions. Remarkably, it has been shown that a human cell cycle protein, when expressed in a mutant yeast defective in the homologous yeast protein, is able to “rescue the defect” of the mutant yeast (that is, to allow the cell to grow normally), thus demonstrating the protein’s ability to function in a very different type of eukaryotic cell. This experimental result, which garnered a Nobel Prize for Paul Nurse, was especially notable because the common ancestor cell of present day yeasts and humans is thought to have lived over a billion years ago. Clearly the eukaryotic cell cycle and the genes and proteins that catalyze it evolved early in biological evolution and have remained quite constant over a very long period of evolutionary time. Importantly, subsequent studies showed that mutations in many yeast cell cycle proteins that allow uncontrolled cell growth also frequently occur in human cancers (Chapter 24), again attesting to the important conserved functions of these proteins in all eukaryotes.

Multicellularity Requires Cell-Cell and Cell Matrix Adhesions

The evolution of multicellular organisms most likely began when cells remained associated in small colonies after division instead of separating into individual cells. A few prokaryotes and several unicellular eukaryotes, such as many fungi and slime molds, exhibit such rudimentary social behavior. The full flowering of multicellularity, however, occurred in eukaryotic organisms whose cells became differentiated and organized into groups, or **tissues**, in which the cells performed a specialized, common function. Metazoans—be they invertebrates like the fruit fly *Drosophila melanogaster* and the roundworm *Caenorhabditis elegans*, or vertebrates such as mice and humans—contain between 13,000 and 23,000 protein-coding genes, about three to four times that of a yeast (Table 1-2). Many of these

genes are conserved among the metazoans and essential for the formation and function of specific tissues and organs.

Animal cells are often “glued” together into a chain, a ball, or a sheet by **cell-adhesion proteins** (often called *cell adhesion molecules*, or CAMs) on their surface (Figure 1-3). Some CAMs bind cells to one another; other types bind cells to the extracellular matrix, forming a cohesive unit. In animals, the matrix cushions cells and allows nutrients to diffuse toward them and waste products to diffuse away. A specialized, especially tough matrix called the **basal lamina**, comprised of multiple proteins such as collagen and polysaccharides, forms a supporting layer underlying cell sheets and prevents the cell aggregates from ripping apart. The cells of higher plants are encased in a network of chambers formed by the interlocking cell walls surrounding the cells, and are connected by cytoplasmic bridges called **plasmodesmata**.

Tissues Are Organized into Organs

The specialized groups of differentiated cells form tissues, which are themselves the major components of organs. For example, the lumen of a blood vessel is lined with a sheetlike layer of endothelial cells, or **endothelium**, which prevents blood cells from leaking out (Figure 1-18). A layer of smooth muscle tissue encircles the endothelium and basal lamina and contracts to limit blood flow. During times of fright, constriction of smaller peripheral vessels forces more blood to the vital organs. The muscle layer of a blood vessel is wrapped in an outer layer of connective tissue, a network of fibers and cells that encase and protect the vessel walls from stretching and rupture. This hierarchy of tissues is copied in other blood vessels, which differ mainly in the thickness of the layers. The wall of a major artery must withstand much stress and is therefore thicker than a minor vessel. The strategy of grouping and layering different tissues is used to build other complex organs as well. In each case the function of the organ is determined by the specific functions of its component tissues, and each type of cell in a tissue produces the specific groups of proteins that enable the tissue to carry out its functions.

FIGURE 1-18 All organs are organized arrangements of various tissues, as illustrated in this cross section of a small artery (arteriole). Blood flows through the vessel lumen (Lu), which is lined by a thin sheet of endothelial cells (EC) forming the endothelium (TI) and by the underlying basal lamina. This tissue adheres to the overlying layer of smooth muscle tissue (TM); contraction of the muscle layer controls blood flow through the vessel. A fibrillar layer of connective tissue (TA) surrounds the vessel and connects it to other tissues. Dr. Richard Kessel & Dr. Randy Kardon/Visuals Unlimited, Inc.

Body Plan and Rudimentary Tissues Form Early in Embryonic Development

The human body consists of some 100 trillion cells, yet it develops from a single cell, the zygote, resulting from fusion of a sperm and an egg. The early stages in the development of an embryo are characterized by rapid cell division (Figure 1-19) and the differentiation of cells into tissues. The embryonic *body plan*, the spatial pattern of cell types (tissues) and body parts, emerges from two influences: a program of genes that

FIGURE 1-19 The first few cell divisions of a fertilized egg set the stage for all subsequent development. A developing mouse embryo is shown at the (a) two-cell, (b) four-cell, and (c) eight-cell stages. The

embryo is surrounded by supporting membranes. The corresponding steps in human development occur during the first few days after fertilization. [Claude Edelman/Photo Researchers, Inc.]

FIGURE 1-20 Similar genes, conserved during evolution, regulate early developmental processes in diverse animals.

(a) Urbilateria is the presumed ancestor of all protostomes and deuterostomes that existed about 600 million years ago. The positions of the nerve chord (violet), surface ectoderm (mainly skin, white), and endoderm (mainly digestive tract and organs, light green) are shown. (b) Highly conserved proteins called Hox proteins are found in both protostomes and deuterostomes and determine the identity of body segments during embryonic development. *Hox* genes are found in clusters on the chromosomes of most or all animals, and encode related transcription factors that control the activities of other genes. In many animals *Hox* genes direct the development of different segments along the head-to-tail axis, as indicated by corresponding colors. Each gene is activated (transcriptionally) in a specific region along the head-to-tail axis and controls the growth of tissues there. For example, in the mouse, a deuterostome, the *Hox* genes are responsible for the distinctive shapes of vertebrae. Mutations affecting *Hox* genes in the fruit fly, a protostome, cause body parts to form in the wrong locations, such as legs in lieu of antennae on the head. In both organisms these genes provide a head-to-tail address and serve to direct the formation of structures in the appropriate places.

specify the pattern of the body, and local cell interactions that induce different parts of the program.

With only a few exceptions, most animals display axial symmetry; that is, their left and right sides mirror each other. This most basic of patterns is encoded in the genome. Developmental biologists have divided bilaterally symmetric animal phyla into two large groups depending on where the mouth and anus form in the early embryo. **Protostomes** develop a mouth close to a transient opening in the early embryo (the **blastopore**) and have a ventral nerve chord; protostomes include all worms, insects, and mollusks. The **deuterostomes** develop an anus close to this transient opening in the embryo and have a dorsal central nervous system; these include echinoderms (such as sea stars and sea urchins) and vertebrates. The bodies of both protostomes and deuterostomes are divided into discrete segments that form early in embryonic development. Protostomes and deuterostomes likely evolved from a common ancestor, termed **Urbilateria**, that lived approximately 600 million years ago (Figure 1-20a).

Patterning genes specify the general organization of an organism, beginning with the major body axes—anterior-posterior, dorsal-ventral, and left-right—and ending with body segments such as the head, chest, abdomen, and tail. The conservation of axial symmetry from the simplest worms to mammals is explained by the presence of conserved patterning genes in their genomes. Some patterning genes encode proteins that control expression of other genes; other patterning genes encode proteins that are important in cell adhesion or in cell signaling. This broad repertoire of patterning genes permits the integration and coordination of events in different parts of the developing embryo and gives each segment in the body its unique identity.

Remarkably, many patterning genes that are often called “master transcription factors,” are highly conserved in both protostomes and deuterostomes (Figure 1-20b). This conservation of body plan reflects evolutionary pressure to preserve the commonalities in the molecular and cellular mechanisms controlling development in different organisms.

Fly eyes and human eyes are very different in structure, function, and nerve connections. Nonetheless, the so-called “master regulator genes” that initiate eye development—*eyeless* in the fly and *Pax6* in the human—encode highly related transcription factors that regulate the activities of other genes and are descended from the same ancestral gene. Mutations in the *eyeless* or *Pax6* genes cause major defects in eye formation (Figure 1-21).

Invertebrates, Fish, and Other Organisms Serve as Experimental Systems for Study of Human Development

Studies of cells in specialized tissues make use of animal and plant model organisms. Nerve cells and muscle cells, for instance, traditionally were studied in mammals or in creatures with especially large or accessible cells, such as the giant neural cells of the squid and sea hare or the flight muscles of birds. More recently, muscle and nerve development have been extensively studied in fruit flies (*Drosophila melanogaster*), roundworms (*Caenorhabditis elegans*), and zebrafish (*Danio rerio*), in which mutants in muscle and nerve formation or function can be readily isolated (Figure 1-13).

Organisms with large-celled embryos that develop outside the mother (e.g., frogs, sea urchins, fish, and chickens) are extremely useful for tracing the fates of cells as they form

FIGURE 1-21 Similar genes, conserved during evolution, regulate organ development in diverse animals. (a) Development of the large compound eyes in fruit flies requires a gene called *eyeless* (named for the mutant phenotype). (b) Flies with inactivated *eyeless* genes lack eyes. (c) Normal human eyes require the gene *Pax6*, the homolog of *eyeless*. (d) People lacking adequate *Pax6* function have the genetic disease *aniridia*, a lack of irises in the eyes. *Pax6* and *eyeless* encode highly related transcription factors that regulate the activities of other genes and are descended from the same ancestral gene.

different tissues and for making extracts for biochemical studies. For instance, a key protein in regulating mitosis was first identified in studies with frog and sea urchin embryos and subsequently purified from their extracts (Chapter 20).

Using recombinant DNA techniques, researchers can engineer specific genes to contain mutations that inactivate or increase production of their encoded proteins. Such genes can be introduced into the embryos of worms, flies, frogs, sea urchins, chickens, mice, a variety of plants, and other organisms, permitting the effects of these mutations to be assessed. This approach is being used extensively to produce mouse

versions of human genetic diseases. Inactivating particular genes by introducing short pieces of interfering RNA allows quick tests of gene functions possible in many organisms.

Mice Are Frequently Used to Generate Models of Human Disease

Mice have one enormous advantage over other experimental organisms: they are the closest to humans of any animal for which powerful genetic approaches are feasible. Mice and humans have shared living structures for millennia, have similar immune systems, and are subject to infection by many of the same pathogens. Both organisms contain about the same number of genes, and about 99 percent of mouse protein-coding genes have homologs in the human, and vice versa. Over 90 percent of mouse and human genomes can be partitioned into regions of conserved synteny—that is, DNA segments that have the same order of unique DNA sequences and genes along a segment of a chromosome. This means that the gene order in the most recent common ancestor of humans and mice has been conserved in both species (Figure 1-22). This conserved synteny is consistent with archeological and other evidence that humans and mice descended from a common mammalian evolutionary ancestor that likely lived about 75 million years ago. Of course mice are not people; relative to humans, mice have expanded families of genes related to immunity, reproduction, and olfaction, likely reflecting the differences between the human and mouse lifestyle.

In Chapter 5 we will learn about the experimental utility of mouse embryonic stem (ES) cells, lines of cells derived from early mouse embryos that can be grown in culture in an undifferentiated state. Using techniques of recombinant DNA, scientists can introduce specific mutations into the mouse genome that mimic the corresponding mutations in human disease. For example, patients with a certain type of cancer accumulate inactivating mutations in a key cell cycle regulatory protein, and the analogous mutation can be introduced into the corresponding mouse gene. These gene-altered ES cells can be injected into an early mouse embryo, which is then implanted into a pseudopregnant female mouse (a mouse treated with hormones to trigger physiological changes needed for pregnancy). If the mice that develop from the injected ES cells exhibit a disease similar to the human cancer, then the link between the disease and mutations in a particular gene or genes is supported. Once mouse models of a human disease are available, further studies on

FIGURE 1-22 Conservation of synteny between human and mouse. Shown is a typical 510,000 base pair (bp) segment of mouse chromosome 12 that shares common ancestry with a 600,000 bp section of human chromosome 14. Blue lines connect the reciprocal unique DNA sequences in the two genomes. Mb, 1 million base pairs. [After Mouse Genome Sequencing Consortium, 2002, *Nature* 420:520.]

(a) T4 bacteriophage

FIGURE 1-23 Viruses must infect a host cell to grow and reproduce. These electron micrographs illustrate some of the structural variety exhibited by viruses. (a) T4 bacteriophage (bracket) attaches to an *E. coli* bacterial cell via a tail structure and injects its DNA, localized in the head, into the cell. Viruses that infect bacteria are called bacteriophages, or simply phages. (b) Tobacco mosaic virus causes a

mottling of the leaves of infected tobacco plants and stunts their growth. (c) Adenovirus causes eye and respiratory tract infections in humans. This virus has an outer membranous envelope from which long glycoprotein spikes protrude. [Part (a) from A. Levine, 1991, *Viruses*, Scientific American Library, p. 20. Part (b) courtesy of R. C. Valentine. Part (c) courtesy of Robley C. Williams, University of California.]

the molecular defects causing the disease can be done and new treatments can be tested, thereby minimizing human exposure to untested treatments.

Viruses Are Cellular Parasites That Are Widely Employed in Molecular Cell Biology Research

Virus-caused diseases are numerous and all too familiar, including chickenpox, influenza, some types of pneumonia, polio, measles, rabies, hepatitis, the common cold, and many others. Viral infections in plants (e.g., dwarf mosaic virus in corn) have a major economic impact on crop production. Almost all viruses have a rather limited host range, infecting only certain bacteria, plants, or animals (Figure 1-23). Viruses are much smaller than cells, on the order of 100 nanometers (nm) in diameter. A virus is typically composed of a protein coat that encloses a core containing the genetic material, which can be either DNA or RNA and carries the information for producing more viruses (Chapter 4). The coat protects a virus from the environment and allows it to stick to, or to enter, specific host cells. In some viruses, the protein coat is surrounded by an outer membrane-like envelope that is formed from the plasma membrane of the infected cell (Figure 14-34).

Because viruses cannot grow or reproduce on their own, a virus must infect a host cell and take over its internal machinery to synthesize viral proteins. All viruses use cellular ribosomes to synthesize viral proteins; most DNA viruses use cellular enzymes for replication of their DNA and for transcription of their DNA into mRNA. Thus studies of virus DNA replication and RNA synthesis are informative of the corresponding cellular processes. When newly made viruses are released by budding from the cell membrane or when the infected cell bursts, the cycle starts anew.

Consider the adenoviruses, which cause eye and respiratory tract infections in humans. Human adenoviruses have a genome of only approximately 35,000 base pairs—about 2 percent the size of a bacterial genome—and encode about 30 proteins, about half of which are conserved among adenoviruses that infect different species. These conserved proteins comprise structural proteins that form parts of the mature virus particle (virion) and proteins that catalyze steps in viral DNA replication. Late in adenovirus infection of human cells, the cell becomes a virtual factory for producing just a few viral proteins: about half of the non-ribosomal RNAs synthesized are viral mRNAs, and most of the proteins produced are viral. In the 1970s—before recombinant DNA techniques were developed—this permitted experiments on adenovirus mRNA synthesis that demonstrated that mature mRNAs had undergone *splicing*, or removal of noncoding sequences (see Figure 1-9). Only later was splicing shown to be a fundamental part of biogenesis of virtually all eukaryotic mRNAs.

A different type of virus, vesicular stomatitis virus, makes a single glycoprotein (a protein with attached carbohydrate chain) that is transported to the plasma membrane and then forms part of the membrane coat of this virus. Studies of this protein (Figures 14-2 and 14-3) elucidated many aspects of the biogenesis of membrane glycoproteins that were later shown to apply to all cellular glycoproteins.

Even today viruses are useful in many aspects of molecular cell biology. Many methods for genetically manipulating cells depend on using viruses to convey DNA molecules into cells. To do this, the portion of the viral genetic material that encodes proteins that are potentially harmful is replaced with other genetic material, including human genes; adenovirus is often employed for this purpose. The altered viruses, or vectors, still can enter cells totting the introduced genes

FIGURE 1-24 The dystrophin glycoprotein complex (DGC) in skeletal muscle cells.

Dystrophin—the protein defective in Duchenne muscular dystrophy—links the actin cytoskeleton to the multiprotein sarcoglycan complex in the plasma membrane. Other proteins in the complex bind to components of the basal lamina, such as laminin, that in turn bind to the collagen fibers that give the basal lamina strength and rigidity. Thus dystrophin is an important member of a group of proteins that links the muscle cell and its internal actin cytoskeleton with the surrounding basal lamina. [Adapted from S. J. Winder, 2001, *Trends Biochem. Sci.* **26**:118, and D. E. Michele and K. P. Campbell, 2003, *J. Biol. Chem.* **278**:15457.]

with them (Chapter 5). One day, diseases caused by defective genes may be treated by using viral vectors to introduce a normal copy of a defective gene into patients. Current research is dedicated to overcoming the considerable obstacles to this *gene therapy* approach, such as getting the introduced genes to work in the right cells at the correct times.

Genetic Diseases Elucidate Important Aspects of Cell Function

Many genetic diseases are caused by mutations in a single protein; studies on humans with these diseases have shed light on the normal function of the protein. As an example, consider Duchenne muscular dystrophy (DMD), the most common type of hereditary muscle-wasting diseases, collectively called muscular dystrophies. DMD is an X chromosome-linked disorder, affecting 1 in 3300 boys, that results in cardiac or respiratory failure, usually in the late teens or early twenties. The first clue to understanding the molecular basis of this disease came from the discovery that people with DMD carry mutations in the gene encoding a protein named dystrophin. This very large protein was later found to be a cytosolic adapter protein, binding to actin filaments that are part of the cytoskeleton (see Figure 1-14) and to a complex of muscle plasma membrane proteins termed the sarcoglycan complex (Figure 1-24). The resulting large multiprotein assemblage, the dystrophin glycoprotein complex (DGC), links the extracellular matrix protein laminin to the cytoskeleton within muscle and other types of cells. Mutations in dystrophin, other DGC components, or laminin can disrupt the DGC-mediated link between the exterior and interior of muscle cells and cause muscle weakness and eventual death. The first step in identifying the entire dystrophin glycoprotein complex involved cloning the dystrophin-encoding gene using DNA from normal individuals and patients with Duchenne muscular dystrophy.

The Following Chapters Present Much Experimental Data That Explains How We Know What We Know About Cell Structure and Function

In subsequent chapters of this book we discuss cellular processes in much greater detail. We begin (Chapter 2) with a discussion of the chemical nature of the building blocks of cells and the basic chemical processes required to understand the macromolecular processes discussed in subsequent chapters. We go on to discuss the structure and function of proteins (Chapter 3) and how the information for their synthesis is encoded in DNA (Chapter 4). Chapter 5 describes many of the techniques used to study genes, gene expression, and protein function. Gene and chromosome structure and the regulation of gene expression are covered in Chapters 6, 7, and 8. Chapter 9 discusses many of the techniques biologists use to culture and fractionate cells and to visualize specific proteins and structures within cells. Biomembrane structure and transport of ions and small molecules across membranes are the topics of Chapters 10 and 11, and Chapter 12 discusses cellular energetics and the functions of mitochondria and chloroplasts. Membrane biogenesis, protein secretion, and protein trafficking—the sorting of proteins to their correct subcellular destinations—are the topics of Chapters 13 and 14. Chapters 15 and 16 discuss the many types of signals and signal receptors used by cells to communicate and regulate their activities. The cytoskeleton and cell movements are discussed in Chapters 17 and 18. Chapter 19 discusses the cell cycle and how cell division is regulated. The interactions among cells and between cells and the extracellular matrix that enable formation of tissues and organs are detailed in Chapter 20. Later chapters of the book discuss important types of specialized cells—stem cells (Chapter 21), nerve cells (Chapter 22), and cells of the immune system (Chapter 23). Chapter 24 discusses cancer and the multiple ways in which cell growth and differentiation can be altered by mutations.

Polarized light microscopic image of crystals of cholesterol. Cholesterol is a water-insoluble molecule that plays a critical structural role in many membranes of animal cells and is a precursor for the synthesis of steroid hormones, bile acids, and vitamin D. Excess deposition of cholesterol in artery walls is a key step in clogging of the arteries, a major cause of heart attacks and strokes. [Courtesy of National High Magnetic Field Laboratory/The Florida State University.]

Chemical Foundations

The life of a cell depends on thousands of chemical interactions and reactions exquisitely coordinated with one another in time and space and under the influence of the cell's genetic instructions and its environment. By understanding at a molecular level these interactions and reactions, we can begin to answer fundamental questions about cellular life: How does a cell extract nutrients and information from its environment? How does a cell convert the energy stored in nutrients into the work of movement or metabolism? How does a cell transform nutrients into the cellular components required for its survival? How does a cell link itself to other cells to form a tissue? How do cells communicate with one another so that a complex, efficiently functioning organism can develop and thrive? One of the goals of *Molecular Cell Biology* is to answer these and other questions about the structure and function of cells and organisms in terms of the properties of individual molecules and ions.

For example, the properties of one such molecule, water, have controlled and continue to control the evolution, structure, and function of all cells. An understanding of biology is not possible without appreciating how the properties of

water control the chemistry of life. Life first arose in a watery environment. Constituting 70–80 percent by weight of most cells, water is the most abundant molecule in biological systems. It is within this aqueous milieu that small molecules and ions, which make up about 7 percent of the weight of living matter, combine into the larger macromolecules and macromolecular assemblies that make up a cell's machinery and architecture and so the remaining mass of organisms. These small molecules include amino acids (the building blocks of proteins), nucleotides (the building blocks of DNA and RNA), lipids (the building blocks of biomembranes), and sugars (the building blocks of complex carbohydrates).

Many of the cell's biomolecules (e.g., sugars) readily dissolve in water; these molecules are called **hydrophilic** ("water liking"). Others (e.g., cholesterol) are oily, fatlike substances that shun water; these are said to be **hydrophobic** ("water fearing"). Still other biomolecules (e.g., phospholipids) contain both hydrophilic and hydrophobic regions; these molecules are said to be **amphipathic** ("both liking"). Phospholipids are used to build the flexible membranes that enclose cells and their internal organelles. The smooth functioning of cells, tissues, and organisms depends on all these molecules,

OUTLINE

2.1	Covalent Bonds and Noncovalent Interactions	24	2.3	Chemical Reactions and Chemical Equilibrium	43
2.2	Chemical Building Blocks of Cells	33	2.4	Biochemical Energetics	48

FIGURE 2-1 Chemistry of life: four key concepts. (a) Molecular complementarity lies at the heart of all biomolecular interactions, as when two proteins with complementary shapes and chemical properties come together to form a tightly bound complex. (b) Small molecules serve as building blocks for larger structures. For example, to generate the information-carrying macromolecule DNA, four small nucleotide building blocks are covalently linked into long strings (polymers), which then wrap around each other to form the double helix. (c) Chemical reactions are reversible, and the distribution of the

chemicals between starting reagents (*left*) and the products of the reactions (*right*) depends on the rate constants of the forward (k_f , upper arrow) and reverse (k_r , lower arrow) reactions. The ratio of these, K_{eq} , provides an informative measure of the relative amounts of products and reactants that will be present at equilibrium. (d) In many cases, the source of energy for chemical reactions in cells is the hydrolysis of the molecule ATP. This energy is released when a high-energy phosphoanhydride bond linking the β and γ phosphates in the ATP molecule (red) is broken by the addition of a water molecule, forming ADP and P_i .

from the smallest to the largest. Indeed, the chemistry of the simple proton (H^+) can be as important to the survival of a human cell as that of each gigantic DNA molecule (the mass of the DNA molecule in human chromosome 1 is 8.6×10^{10} times that of a proton!). The chemical interactions of all of these molecules, large and small, with water and with one another, define the nature of life.

Luckily, although many types of biomolecules interact and react in numerous and complex pathways to form functional cells and organisms, a relatively small number of chemical principles are necessary to understand cellular processes at the molecular level (Figure 2-1). In this chapter we review these key principles, some of which you already know well. We begin with the covalent bonds that connect atoms into molecules and the noncovalent interactions that stabilize groups of atoms within and between molecules. We then consider the basic chemical building blocks of macromolecules and macromolecular assemblies. After reviewing those aspects of chemical equilibrium that are most relevant to

biological systems, we end the chapter with basic principles of biochemical energetics, including the central role of ATP (adenosine triphosphate) in capturing and transferring energy in cellular metabolism.

2.1 Covalent Bonds and Noncovalent Interactions

Strong and weak attractive forces between atoms are the "glue" that holds individual molecules together and permits interactions between different molecules. When two atoms share a single pair of electrons, the result is a **covalent bond**—a type of strong force that holds atoms together in molecules. Sharing of multiple pairs of electrons results in multiple covalent bonds (e.g., "double" or "triple" bonds). The weak attractive forces of **noncovalent interactions** are equally important in determining the properties and functions of biomolecules such as proteins, nucleic acids,

FIGURE 2-2 Covalent bonds form by the sharing of electrons.

Covalent bonds, the strong forces that hold atoms together into molecules, form when atoms share electrons from their outermost electron orbitals. Each atom forms a defined number and geometry of covalent bonds.

carbohydrates, and lipids. In this section, we first review covalent bonds and then discuss the four major types of non-covalent interactions: ionic bonds, hydrogen bonds, Van der Waals interactions, and the hydrophobic effect.

The Electronic Structure of an Atom Determines the Number and Geometry of Covalent Bonds It Can Make

Hydrogen, oxygen, carbon, nitrogen, phosphorus, and sulfur are the most abundant elements in biological molecules. These atoms, which rarely exist as isolated entities, readily form covalent bonds, using electrons in the outermost electron orbitals surrounding their nuclei (Figure 2-2). As a rule, each type of atom forms a characteristic number of covalent bonds with other atoms, with a well-defined geometry determined by the atom's size and by both the distribution of electrons around the nucleus and the number of electrons that it can share. In some cases, the number of stable covalent bonds an atom can make is fixed; carbon, for example, always forms four covalent bonds. In other cases, different numbers of stable covalent bonds are possible; for example, sulfur can form two, four, or six stable covalent bonds.

All the biological building blocks are organized around the carbon atom, which forms four covalent bonds. In these organic biomolecules, each carbon usually bonds to three or four other atoms. (Carbon can also bond to two other atoms, as in the linear molecule carbon dioxide, CO_2 , which has two carbon-oxygen double bonds ($\text{O}=\text{C}=\text{O}$); however, such bond arrangements of carbon are not found in biological building blocks.) As illustrated in Figure 2-3a for formaldehyde, carbon can bond to three atoms, all in a common plane. The carbon atom forms two single bonds with two atoms and one double bond (two shared electron pairs) with the third atom. In the absence of other constraints, atoms joined by a single bond generally can rotate freely about the bond axis, whereas those connected by a double bond cannot. The rigid planarity imposed by double bonds has enormous

significance for the shapes and flexibility of biomolecules such as phospholipids, proteins, and nucleic acids.

Carbon can also bond to four rather than three atoms. As illustrated by methane (CH_4), when carbon is bonded to four other atoms, the angle between any two bonds is 109.5° and the positions of bonded atoms define the four points of a tetrahedron (Figure 2-3b). This geometry defines the structures of many biomolecules. A carbon (or any other) atom bonded to four dissimilar atoms or groups in a nonplanar configuration is said to be asymmetric. The tetrahedral orientation of bonds formed by an asymmetric carbon atom can be arranged in three-dimensional space in two different ways, producing molecules that are mirror images of each other, a property called *chirality* (from the Greek word *cheir*, meaning "hand") (Figure 2-4). Such molecules are called *optical isomers*, or *stereoisomers*. Many molecules in cells contain at least one asymmetric carbon atom, often called a *chiral carbon* atom. The different stereoisomers of a molecule usually have completely different biological activities because the arrangement of atoms within their structures, and thus their ability to interact with other molecules, differs.

(a) Formaldehyde

(b) Methane

FIGURE 2-3 Geometry of bonds when carbon is covalently

linked to three or four other atoms. (a) A carbon atom can be bonded to three atoms, as in formaldehyde (CH_2O). In this case, the carbon-bonding electrons participate in two single bonds and one double bond, which all lie in the same plane. Unlike atoms connected by a single bond, which usually can rotate freely about the bond axis, those connected by a double bond cannot. (b) When a carbon atom forms four single bonds, as in methane (CH_4), the bonded atoms (all H in this case) are oriented in space in the form of a tetrahedron. The letter representation on the left clearly indicates the atomic composition of the molecule and the bonding pattern. The ball-and-stick model in the center illustrates the geometric arrangement of the atoms and bonds, but the diameters of the balls representing the atoms and their nonbonding electrons are unrealistically small compared with the bond lengths. The sizes of the electron clouds in the space-filling model on the right more accurately represent the structure in three dimensions.

FIGURE 2-4 Stereoisomers. Many molecules in cells contain at least one asymmetric carbon atom. The tetrahedral orientation of bonds formed by an asymmetric carbon atom can be arranged in three-dimensional space in two different ways, producing molecules that are mirror images, or stereoisomers, of each other. Shown here is the common structure of an amino acid, with its central asymmetric carbon and four attached groups, including the R group, discussed in Section 2.2. Amino acids can exist in two mirror-image forms, designated L and D. Although the chemical properties of such stereoisomers are identical, their biological activities are distinct. Only L amino acids are found in proteins.

Some drugs are mixtures of the stereoisomers of small molecules in which only one stereoisomer has the biological activity of interest. The use of a pure single stereoisomer of the chemical in place of the mixture may result in a more potent drug with reduced side effects. For example, one stereoisomer of the antidepressant drug citalopram (Celexa) is 170 times more potent than the other. Some stereoisomers have very different activities. Darvon is a pain reliever, whereas its stereoisomer, Novrad (*Darvon* spelled backward), is a cough suppressant. One stereoisomer of ketamine is an anesthetic, whereas the other causes hallucinations. ■

The typical number of covalent bonds formed by other atoms common to biomolecules is shown in Table 2-1. A hydrogen atom forms only one covalent bond. An atom of oxygen usually forms only two covalent bonds but has two additional pairs of electrons that can participate in noncovalent interactions. Sulfur forms two covalent bonds in hydrogen sulfide (H_2S) but also can accommodate six covalent bonds, as in sulfuric acid (H_2SO_4) and its sulfate derivatives. Nitrogen and phosphorus each have five electrons to share. In ammonia (NH_3), the nitrogen atom forms three covalent bonds; the pair of electrons around the atom not involved in a covalent bond can take part in noncovalent interactions. In the ammonium ion (NH_4^+), nitrogen forms four covalent bonds, which have a tetrahedral geometry. Phosphorus commonly forms five covalent bonds, as in phosphoric acid (H_3PO_4) and its phosphate derivatives, which form the backbone of nucleic acids. Phosphate groups covalently attached to proteins play a key role in regulating the activity of many proteins, and the central molecule in cellular energetics,

ATP, contains three phosphate groups (see Section 2.4). A summary of common covalent linkages and functional groups, which confer distinctive chemical properties to the molecules of which they are a part, is provided in Table 2-2.

Electrons May Be Shared Equally or Unequally in Covalent Bonds

The extent of an atom's ability to attract an electron is called its *electronegativity*. In a bond between atoms with identical or similar electronegativities, the bonding electrons are essentially shared equally between the two atoms, as is the case for most carbon-carbon single bonds ($\text{C}-\text{C}$) and carbon-hydrogen single bonds ($\text{C}-\text{H}$). Such bonds are called **non-polar**. In many molecules, the bonded atoms have different electronegativities, resulting in unequal sharing of electrons. The bond between them is said to be **polar**.

One end of a polar bond has a partial negative charge (δ^-), and the other end has a partial positive charge (δ^+). In an $\text{O}-\text{H}$ bond, for example, the greater electronegativity of the oxygen atom relative to hydrogen results in the electrons spending more time around the oxygen atom than the hydrogen. Thus the $\text{O}-\text{H}$ bond possesses an electric **dipole**, a positive charge separated from an equal but opposite negative charge. The amount of δ^- charge on the oxygen atom of a $\text{O}-\text{H}$ dipole is approximately 25 percent of that of an electron, with an equivalent and opposite δ^+ charge on the H atom. A common quantitative measure of the extent of charge separation, or strength, of a dipole is called the **dipole moment**, μ , which for a chemical bond is the product of the partial charge on each atom and the distance between the two atoms. For a molecule with multiple dipoles, the amount of charge separation for the molecule as a whole depends in part on the dipole moments of all of its individual chemical bonds and in part on the geometry of the molecule (relative orientations of the individual dipole moments). Consider the example

of water (H_2O), which has two O—H bonds and thus two individual bond dipole moments. If water were a linear molecule with the two bonds on exact opposite sides of the O atom, the two dipoles on each end of the molecule would be identical in strength but would be oriented in opposite directions. The two dipole moments would cancel each other and the dipole moment of molecule as a whole would be zero. However, because water is a V-shaped molecule, with the individual dipoles of its two O—H bonds both pointing toward the oxygen, one end of the water molecule (the end with the oxygen atom) has a partial negative charge and the other end (the one with the two hydrogen atoms) has a partial positive charge. As a consequence, the molecule as a whole is a dipole with a well-defined dipole moment (Figure 2-5). This dipole

FIGURE 2-5 The dipole nature of a water molecule. The symbol δ represents a partial charge (a weaker charge than the one on an electron or a proton). Because of the difference in the electronegativities of H and O, each of the polar H—O bonds in water is a dipole. The sizes and directions of the dipoles of each of the bonds determine the net distance and amount of charge separation, or dipole moment, of the molecule.

moment and the electronic properties of the oxygen and hydrogen atoms allow water to form electrostatic, noncovalent interactions with other waters and with other molecules. These interactions play a critical role in almost every biochemical interaction in cells and organisms and will be discussed shortly.

Another important example of polarity is the O=P double bond in H_3PO_4 . In the structure of H_3PO_4 shown on the left below, lines represent single and double bonds and non-bonding electrons are shown as pairs of dots:

Because of the polarity of the O=P double bond, the H_3PO_4 can also be represented by the structure on the right, in which one of the electrons from the P=O double bond has accumulated around the O atom, giving it a negative charge and leaving the P atom with a positive charge. These charges are important in noncovalent interactions. Neither of these two models precisely describes the electronic state of H_3PO_4 . The actual structure can be considered to be an intermediate, or hybrid, between these two representations, as indicated by the double-headed arrow between them. Such intermediate structures are called *resonance hybrids*.

FIGURE 2-6 Relative energies of covalent bonds and noncovalent interactions. Bond energies are defined as the energy required to break a particular type of linkage. Shown here are the energies required to break a variety of linkages, arranged on a log scale. Covalent bonds, including those for single (C—C) and double (C=C) carbon-carbon bonds, are one to two powers of 10 stronger than noncovalent interactions. The latter are somewhat greater than the thermal energy of the environment at normal room temperature (25 °C). Many biological processes are coupled to the energy released during hydrolysis of a phosphoanhydride bond in ATP.

Covalent Bonds Are Much Stronger and More Stable Than Noncovalent Interactions

Covalent bonds are considered to be strong because the energies required to break them are much greater than the thermal energy available at room temperature (25 °C) or body temperature (37 °C). As a consequence, they are stable at these temperatures. For example, the thermal energy at 25 °C is approximately 0.6 kilocalorie per mole (kcal/mol), whereas the energy required to break the C—C bond in ethane is about 140 times larger (Figure 2-6). Consequently, at room temperature (25 °C), fewer than 1 in 10^{12} ethane molecules is broken into a pair of $\cdot\text{CH}_3$ molecules, each containing an unpaired, nonbonding electron (called a radical).

Covalent single bonds in biological molecules have energies similar to the energy of the C—C bond in ethane. Because more electrons are shared between atoms in double bonds, they require more energy to break than single bonds. For instance, it takes 84 kcal/mol to break a single C—O bond but 170 kcal/mol to break a C=O double bond. The most common double bonds in biological molecules are C=O, C=N, C=C, and P=O.

In contrast, the energy required to break noncovalent interactions is only 1–5 kcal/mol, much less than the bond energies of covalent bonds (see Figure 2-6). Indeed, noncovalent interactions are weak enough that they are constantly being formed and broken at room temperature. Although these interactions are weak and have a transient existence at physiological temperatures (25–37 °C), multiple noncovalent interactions can, as we will see, act together to produce highly stable and specific associations between different parts of a large molecule or between different macromolecules. Protein-protein and protein-nucleic acid interactions are good examples of noncovalent interactions. Below, we review the four main types of noncovalent interactions and then consider their roles in the binding of biomolecules to one another and to other molecules.

Ionic Interactions Are Attractions Between Oppositely Charged Ions

Ionic interactions result from the attraction of a positively charged ion—a **cation**—for a negatively charged ion—an **anion**. In sodium chloride (NaCl), for example, the bonding electron

contributed by the sodium atom is completely transferred to the chlorine atom. (Figure 2-7a). Unlike covalent bonds, ionic interactions do not have fixed or specific geometric orientations because the electrostatic field around an ion—its attraction for an opposite charge—is uniform in all directions. In solid NaCl, oppositely charged ions pack tightly together in an alternating pattern, forming the highly ordered crystalline array typical of salt crystals (Figure 2-7b). The energy required to break an ionic interaction depends on the distance between the ions and the electrical properties of the environment of the ions.

When solid salts dissolve in water, the ions separate from one another and are stabilized by their interactions with water molecules. In aqueous solutions, simple ions of biological significance, such as Na^+ , K^+ , Ca^{2+} , Mg^{2+} , and Cl^- , are hydrated, surrounded by a stable shell of water molecules held in place by ionic interactions between the central ion and the oppositely charged end of the water dipole (Figure 2-7c). Most ionic compounds dissolve readily in water because the energy of hydration, the energy released when ions tightly bind water molecules and spread out in an aqueous solution, is greater than the lattice energy that stabilizes the crystal structure. Parts or all of the aqueous *hydration shell* must be removed from ions when they directly interact with proteins. For example, water of hydration is lost when ions pass through protein pores in the cell membrane during nerve conduction.

The relative strength of the interaction between two oppositely charged ions, A^- and C^+ , depends on the concentration of other ions in a solution. The higher the concentration of other ions (e.g., Na^+ and Cl^-), the more opportunities A^- and C^+ have to interact ionically with these other ions and thus the lower the energy required to break the interaction between A^- and C^+ . As a result, increasing the concentrations of salts such as NaCl in a solution of biological molecules can weaken and even disrupt the ionic interactions holding the biomolecules together.

Hydrogen Bonds Are Noncovalent Interactions That Determine the Water Solubility of Uncharged Molecules

A **hydrogen bond** is the interaction of a partially positively charged hydrogen atom in a molecular dipole, such as water,

FIGURE 2-7 Electrostatic interactions of oppositely charged ions of salt (NaCl) in crystals and in aqueous solution. (a) In crystalline table salt, sodium atoms are positively charged ions (Na⁺) due to the loss of one electron each, whereas chloride atoms are correspondingly negatively charged (Cl⁻) by gaining one electron each. (b) In solid form, ionic compounds form neatly ordered arrays, or crystals, of tightly packed ions in which the positive and negatively charged ions counter-

balance each other. (c) When the crystals are dissolved in water, the ions separate and their charges, no longer balanced by immediately adjacent ions of opposite charge, are stabilized by interactions with polar water. Water molecules and the ions are held together by electrostatic interactions between the charges on the ion and the partial charges on the water's oxygen and hydrogen atoms. In aqueous solutions, all ions are surrounded by a hydration shell of water molecules.

with unpaired electrons from another atom, either in the same or a different molecule. Normally, a hydrogen atom forms a covalent bond with only one other atom. However, a hydrogen atom covalently bonded to an electronegative donor atom D may form an additional weak association, the hydrogen bond, with an acceptor atom A, which must have a nonbonding pair of electrons available for the interaction:

The length of the covalent D—H bond is a bit longer than it would be if there were no hydrogen bond because the

acceptor “pulls” the hydrogen away from the donor. An important feature of all hydrogen bonds is directionality. In the strongest hydrogen bonds, the donor atom, the hydrogen atom, and the acceptor atom all lie in a straight line. Nonlinear hydrogen bonds are weaker than linear ones; still, multiple nonlinear hydrogen bonds help to stabilize the three-dimensional structures of many proteins.

Hydrogen bonds are both longer and weaker than covalent bonds between the same atoms. In water, for example, the distance between the nuclei of the hydrogen and oxygen atoms of adjacent, hydrogen-bonded molecules is about 0.27 nm, about twice the length of the covalent O—H bonds within a single water molecule (Figure 2-8a). The strength of a hydrogen bond between water molecules (approximately 5 kcal/mol) is much

FIGURE 2-8 Hydrogen bonding of water with itself and with other compounds. Each pair of nonbonding outer electrons in an oxygen or a nitrogen atom can accept a hydrogen atom in a hydrogen bond. The hydroxyl and the amino groups can also form hydrogen bonds with water. (a) in liquid water, each water molecule forms transient hydrogen bonds with several others, creating a dynamic

network of hydrogen-bonded molecules. (b) Water also can form hydrogen bonds with alcohols and amines, accounting for the high solubility of these compounds. (c) The peptide group and ester group, which are present in many biomolecules, commonly participate in hydrogen bonds with water or polar groups in other molecules.

FIGURE 2-9 Distribution of bonding and outer nonbonding electrons in the peptide group. Shown here is a peptide bond linking two amino acids within a protein called crambin. No protein has been structurally characterized at higher resolution than crambin. The black lines represent the covalent bonds between atoms. The red (negative) and blue (positive) lines represent contours of charge determined using x-ray crystallography and computational methods. The greater the number of contour lines, the higher the charge. The high density of red contour lines between atoms represents the covalent bonds (shared electron pairs). The two sets of red contour lines emanating from the oxygen (O) and not falling on a covalent bond (black line) represent the two pairs of nonbonded electrons on the oxygen that are available to participate in hydrogen bonding. The high density of blue contour lines near the hydrogen (H) bonded to nitrogen (N) represents a partial positive charge, indicating that this H can act as a donor in hydrogen bonding. [From C. Jelsch et al., 2000, *Proc. Nat'l. Acad. Sci. USA* 97:3171. Courtesy of M. M. Teeter.]

weaker than a covalent O—H bond (roughly 110 kcal/mol), although it is greater than that for many other hydrogen bonds in biological molecules (1–2 kcal/mol). Extensive intermolecular hydrogen bonding between water molecules accounts for many of its key properties, including its unusually high melting and boiling points and its ability to dissolve many other molecules.

The solubility of uncharged substances in an aqueous environment depends largely on their ability to form hydrogen bonds with water. For instance, the hydroxyl group (—OH) in an alcohol (XCH_2OH) and the amino group (— NH_2) in amines (XCH_2NH_2) can form several hydrogen bonds with water, allowing these molecules to dissolve in water to high concentrations (Figure 2-8b). In general, molecules with polar bonds that easily form hydrogen bonds with water, as well as charged molecules and ions that interact with the dipole in water, can readily dissolve in water; that is, they are hydrophilic. Many biological molecules contain, in addition to hydroxyl and amino groups, peptide and ester groups, which form hydrogen bonds with water via otherwise nonbonded electrons on their carbonyl oxygens (Figure 2-8c). X-ray crystallography combined with computational analysis permits an accurate depiction of the distribution of the outermost unbonded electrons of atoms as well as the electrons in covalent bonds, as illustrated in Figure 2-9.

Van der Waals Interactions Are Weak Attractive Interactions Caused by Transient Dipoles

When any two atoms approach each other closely, they create a weak, nonspecific attractive force called a **van der Waals interaction**. These nonspecific interactions result from the momentary random fluctuations in the distribution of the electrons of any atom, which give rise to a transient unequal distribution of electrons. If two noncovalently bonded atoms are close enough, electrons of one atom will perturb

the electrons of the other. This perturbation generates a transient dipole in the second atom, and the two dipoles will attract each other weakly (Figure 2-10). Similarly, a polar covalent bond in one molecule will attract an oppositely oriented dipole in another.

Van der Waals interactions, involving either transiently induced or permanent electric dipoles, occur in all types of molecules, both polar and nonpolar. In particular, van der Waals interactions are responsible for the cohesion between nonpolar molecules such as heptane, $\text{CH}_3-(\text{CH}_2)_5-\text{CH}_3$, that cannot form hydrogen bonds or ionic interactions with each other. The strength of van der Waals interactions

FIGURE 2-10 Two oxygen molecules in van der Waals contact. In this model, red indicates negative charge and blue indicates positive charge. Transient dipoles in the electron clouds of all atoms give rise to weak attractive forces, called van der Waals interactions. Each type of atom has a characteristic van der Waals radius at which van der Waals interactions with other atoms are optimal. Because atoms repel one another if they are close enough together for their outer electrons to overlap without being shared in a covalent bond, the van der Waals radius is a measure of the size of the electron cloud surrounding an atom. The covalent radius indicated here is for the double bond of $\text{O}=\text{O}$; the single-bond covalent radius of oxygen is slightly longer.

decreases rapidly with increasing distance; thus these noncovalent interactions can form only when atoms are quite close to one another. However, if atoms get too close together, the negative charges of their electrons create a repulsive force. When the van der Waals attraction between two atoms exactly balances the repulsion between their two electron clouds, the atoms are said to be in van der Waals contact. The strength of the van der Waals interaction is about 1 kcal/mol, weaker than typical hydrogen bonds and only slightly higher than the average thermal energy of molecules at 25 °C. Thus multiple van der Waals interactions, a van der Waals interaction together with other noncovalent interactions, or both are required to form stable attractions within and between molecules.

The Hydrophobic Effect Causes Nonpolar Molecules to Adhere to One Another

Because nonpolar molecules do not contain charged groups, do not possess a dipole moment, or become hydrated, they are insoluble or almost insoluble in water; that is, they are hydrophobic. The covalent bonds between two carbon atoms and between carbon and hydrogen atoms are the most common nonpolar bonds in biological systems. **Hydrocarbons**—molecules made up only of carbon and hydrogen—are virtually insoluble in water. Large triacylglycerols (also known as triglycerides), which make up animal fats and vegetable oils, also are insoluble in water. As we will see later, the major part of these molecules consists of long hydrocarbon chains. After being shaken in water, triacylglycerols form a separate phase. A familiar example is the separation of oil from the water-based vinegar in an oil-and-vinegar salad dressing.

Nonpolar molecules or nonpolar parts of molecules tend to aggregate in water owing to a phenomenon called the **hydrophobic effect**. Because water molecules cannot form hydrogen bonds with nonpolar substances, they tend to form “cages” of relatively rigid hydrogen-bonded pentagons and hexagons around nonpolar molecules (Figure 2-11, *left*). This state is energetically unfavorable because it decreases the entropy, or randomness, of the population of water molecules. (The role of entropy in chemical systems is discussed in Section 2.4.) If nonpolar molecules in an aqueous environment aggregate with their hydrophobic surfaces facing each other, the net hydrophobic surface area exposed to water is reduced (Figure 2-11, *right*). As a consequence, less water is needed to form the cages surrounding the nonpolar molecules, entropy increases relative to the unaggregated state, and an energetically more favorable state is reached. In a sense, then, water squeezes the nonpolar molecules into spontaneously forming aggregates. Rather than constituting an attractive force such as in hydrogen bonds, the hydrophobic effect results from an avoidance of an unstable state—that is, extensive water cages around individual nonpolar molecules.

Nonpolar molecules can also associate, albeit weakly, through van der Waals interactions. The net result of the

FIGURE 2-11 Schematic depiction of the hydrophobic effect.

Cages of water molecules that form around nonpolar molecules in solution are more ordered than water molecules in the surrounding bulk liquid. Aggregation of nonpolar molecules reduces the number of water molecules involved in highly ordered cages, resulting in a higher-entropy, more energetically favorable state (*right*) compared with the unaggregated state (*left*).

hydrophobic effect and van der Waals interactions is a very powerful tendency for hydrophobic molecules to interact with one another, not with water. Simply put, *like dissolves like*. Polar molecules dissolve in polar solvents such as water; nonpolar molecules dissolve in nonpolar solvents such as hexane.

One well-known hydrophobic molecule is cholesterol (see the structure in Section 2.2). Cholesterol, as well as triglycerides and other poorly water-soluble molecules, is called a lipid. Unlike hydrophilic molecules such as glucose or amino acids, lipids cannot readily dissolve in the blood, which is an aqueous circulatory system for transporting molecules and cells throughout the body. Instead, lipids such as cholesterol must be packaged into hydrophilic carriers that can themselves dissolve in the blood and be transported throughout the body. There can be hundreds to thousands of lipids packed into the center, or core, of each carrier. The hydrophobic core is surrounded by amphipathic molecules that have hydrophilic parts that interact with water and hydrophobic parts that interact with each other and the core. The packaging of these lipids into special carriers, called lipoproteins (discussed in Chapter 14), permits their efficient transport in blood and is reminiscent of the containerization of cargo for efficient long-distance transport via cargo ships, trains and trucks. High-density lipoprotein (HDL) and low-density lipoprotein (LDL) are two such lipoprotein carriers that are associated with either reduced or increased heart disease, respectively, and are therefore often referred to as “good” and “bad” cholesterol. Actually, the cholesterol molecules and their derivatives that are carried by both HDL and LDL are essentially identical and in themselves neither

“good” nor “bad.” However, HDL and LDL have different effects on cells, and as a consequence LDL contributes to and HDL protects from the clogging of the arteries (known as *atherosclerosis*) and consequent heart disease and stroke. Thus LDL is known as “bad” cholesterol. ■

Molecular Complementarity Due to Noncovalent Interactions Leads to a Lock-and-Key Fit Between Biomolecules

Both inside and outside cells, ions and molecules constantly collide. The higher the concentration of any two types of molecule, the more likely they are to encounter each other. When two molecules encounter each other, they most likely will simply bounce apart because the noncovalent interactions that would bind them together are weak and have a transient existence at physiological temperatures. However, molecules that exhibit **molecular complementarity**, a lock-and-key kind of fit between their shapes, charges, or other physical properties, can form multiple noncovalent interactions at close range. When two such structurally complementary molecules bump into each other, these multiple interactions cause them to stick together, or bind.

Figure 2-12 illustrates how multiple, different weak interactions can cause two proteins to bind together tightly. Almost any other arrangement of the same groups on the two surfaces would not allow the molecules to bind so tightly. Such molecular complementarity between regions within a protein molecule allow it to fold into a unique three-dimensional shape (see Chapter 3); it is also what

holds the two chains of DNA together in a double helix (see Chapter 4). Similar interactions underlie the association of groups of molecules into multimolecular assemblies, or complexes, leading, for example, to the formation of muscle fibers, to the glue-like associations between cells in solid tissues, and to numerous other cellular structures.

Depending on the number and strength of the noncovalent interactions between the two molecules and on their environment, their binding may be tight or loose and, as a consequence, either long lasting or transient. The higher the *affinity* of two molecules for each other, the better the molecular “fit” between them, the more noncovalent interactions can form, and the tighter they can bind together. An important quantitative measure of affinity is the binding dissociation constant K_d , described later.

As we discuss in Chapter 3, nearly all the chemical reactions that occur in cells also depend on the binding properties of enzymes. These proteins not only speed up, or catalyze, reactions but also do so with a high degree of *specificity*, a reflection of their ability to bind tightly to only one or a few related molecules. The specificity of intermolecular interactions and reactions, which depends on molecular complementarity, is essential for many processes critical to life.

KEY CONCEPTS of Section 2.1

Covalent Bonds and Noncovalent Interactions

- Covalent bonds consist of pairs of electrons shared by two atoms. Covalent bonds arrange the atoms of a molecule into a specific geometry.
- Covalent bonds are stable in biological systems because the relatively high energies required to break them (50–200 kcal/mol) are much larger than the thermal kinetic energy available at room (25 °C) or body (37 °C) temperatures.
- Many molecules in cells contain at least one asymmetric carbon atom, which is bonded to four dissimilar atoms. Such molecules can exist as optical isomers (mirror images), designated D and L (see Figure 2-4), which have different biological activities. In biological systems, nearly all sugars are D isomers, whereas nearly all amino acids are L isomers.
- Electrons may be shared equally or unequally in covalent bonds. Atoms that differ in electronegativity form polar covalent bonds, in which the bonding electrons are distributed unequally. One end of a polar bond has a partial positive charge and the other end has a partial negative charge (see Figure 2-5).
- Noncovalent interactions between atoms are considerably weaker than covalent bonds, with energies ranging from about 1–5 kcal/mol (see Figure 2-6).
- Four main types of noncovalent interactions occur in biological systems: ionic bonds, hydrogen bonds, van der Waals interactions, and interactions due to the hydrophobic effect.
- Ionic bonds result from the electrostatic attraction between the positive and negative charges of ions. In aqueous

FIGURE 2-12 Molecular complementarity permits tight protein bonding via multiple noncovalent interactions. The complementary shapes, charges, polarity, and hydrophobicity of two protein surfaces permit multiple weak interactions, which in combination produce a strong interaction and tight binding. Because deviations from molecular complementarity substantially weaken binding, a particular surface region of any given biomolecule usually can bind tightly to only one or a very limited number of other molecules. The complementarity of the two protein molecules on the left permits them to bind much more tightly than the two noncomplementary proteins on the right.

solutions, all cations and anions are surrounded by a shell of bound water molecules (see Figure 2-7c). Increasing the salt (e.g., NaCl) concentration of a solution can weaken the relative strength of and even break the ionic bonds between biomolecules.

- In a hydrogen bond, a hydrogen atom covalently bonded to an electronegative atom associates with an acceptor atom whose nonbonding electrons attract the hydrogen (see Figure 2-8).
- Weak and relatively nonspecific van der Waals interactions result from the attraction between transient dipoles associated with all molecules. They form when two atoms approach each other closely (see Figure 2-10).
- In an aqueous environment, nonpolar molecules or nonpolar parts of larger molecules are driven together by the hydrophobic effect, thereby reducing the extent of their direct contact with water molecules (see Figure 2-11).
- Molecular complementarity is the lock-and-key fit between molecules whose shapes, charges, and other physical properties are complementary. Multiple noncovalent interactions can form between complementary molecules, causing them to bind tightly (see Figure 2-12), but not between molecules that are not complementary.
- The high degree of binding specificity that results from molecular complementarity is one of the features that underlies intermolecular interactions in biology and thus is essential for many processes critical to life.

2.2 Chemical Building Blocks of Cells

A common theme in biology is the construction of large **macromolecules** and macromolecular structures out of smaller molecular subunits. Often these subunits are similar or identical. The three main types of biological macromolecules—**proteins**, **nucleic acids**, and **polysaccharides**—are all polymers composed of multiple covalently linked building block small molecules, or **monomers** (Figure 2-13). Proteins are linear polymers containing around 10 to several thousand amino acids linked by **peptide bonds**. Nucleic acids are linear polymers containing hundreds to millions of nucleotides linked by **phosphodiester bonds**. Polysaccharides are linear or branched polymers of monosaccharides (sugars) such as glucose linked by **glycosidic bonds**. Although the actual mechanisms of covalent bond formation between monomers are complex and will be discussed later, the formation of a covalent bond between two monomer molecules usually involves the net loss of a hydrogen (H) from one monomer and a hydroxyl (OH) from the other monomer—or the net loss of one water molecule—and can therefore be thought of as a *dehydration reaction*. The breakdown, or cleavage, of this bond in the polymer that releases a monomeric subunit involves the reverse reaction or the addition of water, called

hydrolysis. These bonds linking the monomers together are normally stable under normal biological conditions (e.g., 37 °C, neutral pH), and so these biopolymers are stable and can perform a wide variety of jobs in cells, such as store information, catalyze chemical reactions, serve as structural elements in defining cell shape and movement, and many others.

Macromolecular structures can also be assembled using noncovalent interactions. The two-ply, or “bilayer” structure of cellular membranes is built up by the noncovalent assembly of many thousands of small molecules called phospholipids (see Figure 2-13). In this chapter, we focus on the chemical building blocks making up cells—amino acids, nucleotides, sugars, and phospholipids. The structure, function, and assembly of proteins, nucleic acids, polysaccharides, and biomembranes are discussed in subsequent chapters.

Amino Acids Differing Only in Their Side Chains Compose Proteins

The monomeric building blocks of proteins are 20 **amino acids**, which—when incorporated into a protein polymer—are sometimes called **residues**. All amino acids have a characteristic structure consisting of a central **alpha carbon atom** (C_α) bonded to four different chemical groups: an amino (NH_2) group, a carboxyl or carboxylic acid ($COOH$) group (hence the name *amino acid*), a hydrogen (H) atom, and one variable group, called a **side chain** or **R group**. Because the α carbon in all amino acids except glycine is asymmetric, these molecules can exist in two mirror-image forms called by convention the **D** (dextro) and the **L** (levo) isomers (see Figure 2-4). The two isomers cannot be interconverted (one made identical to the other) without breaking and then re-forming a chemical bond in one of them. With rare exceptions, only the L forms of amino acids are found in proteins. However, D amino acids are prevalent in bacterial cell walls and other microbial products.

To understand the three-dimensional structures and functions of proteins, discussed in detail in Chapter 3, you must be familiar with some of the distinctive properties of amino acids, which are determined in part by their side chains. You need not memorize the detailed structure of each type of side chain to understand how proteins work because amino acids can be classified into several broad categories based on the size, shape, charge, hydrophobicity (a measure of water solubility), and chemical reactivity of the side chains (Figure 2-14). However, you should be familiar with the general properties of each category.

Amino acids with nonpolar side chains are called **hydrophobic** and are poorly soluble in water. The larger the nonpolar side chain, the more hydrophobic the amino acid. The side chains of *alanine*, *valine*, *leucine*, and *isoleucine* are linear or branched hydrocarbons that do not form a ring and are therefore called **aliphatic amino acids**. These amino acids are all nonpolar, as is *methionine*, which is similar except it contains one sulfur atom. *Phenylalanine*, *tyrosine*, and *tryptophan* have large, hydrophobic, aromatic rings in their side chains. In later chapters, we will see in detail how hydrophobic side chains under the influence of the hydrophobic effect

FIGURE 2-13 Overview of the cell's principal chemical building blocks. (Top) The three major types of biological macromolecules are each assembled by the polymerization of multiple small molecules (monomers) of a particular type: proteins from amino acids (see Chapter 3), nucleic acids from nucleotides (see Chapter 4), and

polysaccharides from monosaccharides (sugars). Each monomer is covalently linked into the polymer by a reaction whose net result is loss of a water molecule (dehydration). (Bottom) In contrast, phospholipid monomers noncovalently assemble into a bilayer structure, which forms the basis of all cellular membranes (see Chapter 10).

often pack in the interior of proteins or line the surfaces of proteins that are embedded within hydrophobic regions of biomembranes.

Amino acids with polar side chains are called hydrophilic; the most hydrophilic of these amino acids is the subset with side chains that are charged (ionized) at the pH typical of biological fluids (~ 7), both inside and outside the cell (see Section 2.3). *Arginine* and *lysine* have positively charged side chains and are called basic amino acids; *aspartic acid* and *glutamic acid* have negatively charged side chains due to the carboxylic acid groups in their side chains (their charged forms are called *aspartate* and *glutamate*) and are called acidic. A fifth amino acid, *histidine*, has a side chain containing a ring with two nitrogens, called imidazole, which can

shift from being positively charged to uncharged depending on small changes in the acidity of its environment:

The activities of many proteins are modulated by shifts in environmental acidity (pH) through protonation or deprotonation of histidine side chains. *Asparagine* and *glutamine* are uncharged but have polar side chains containing amide

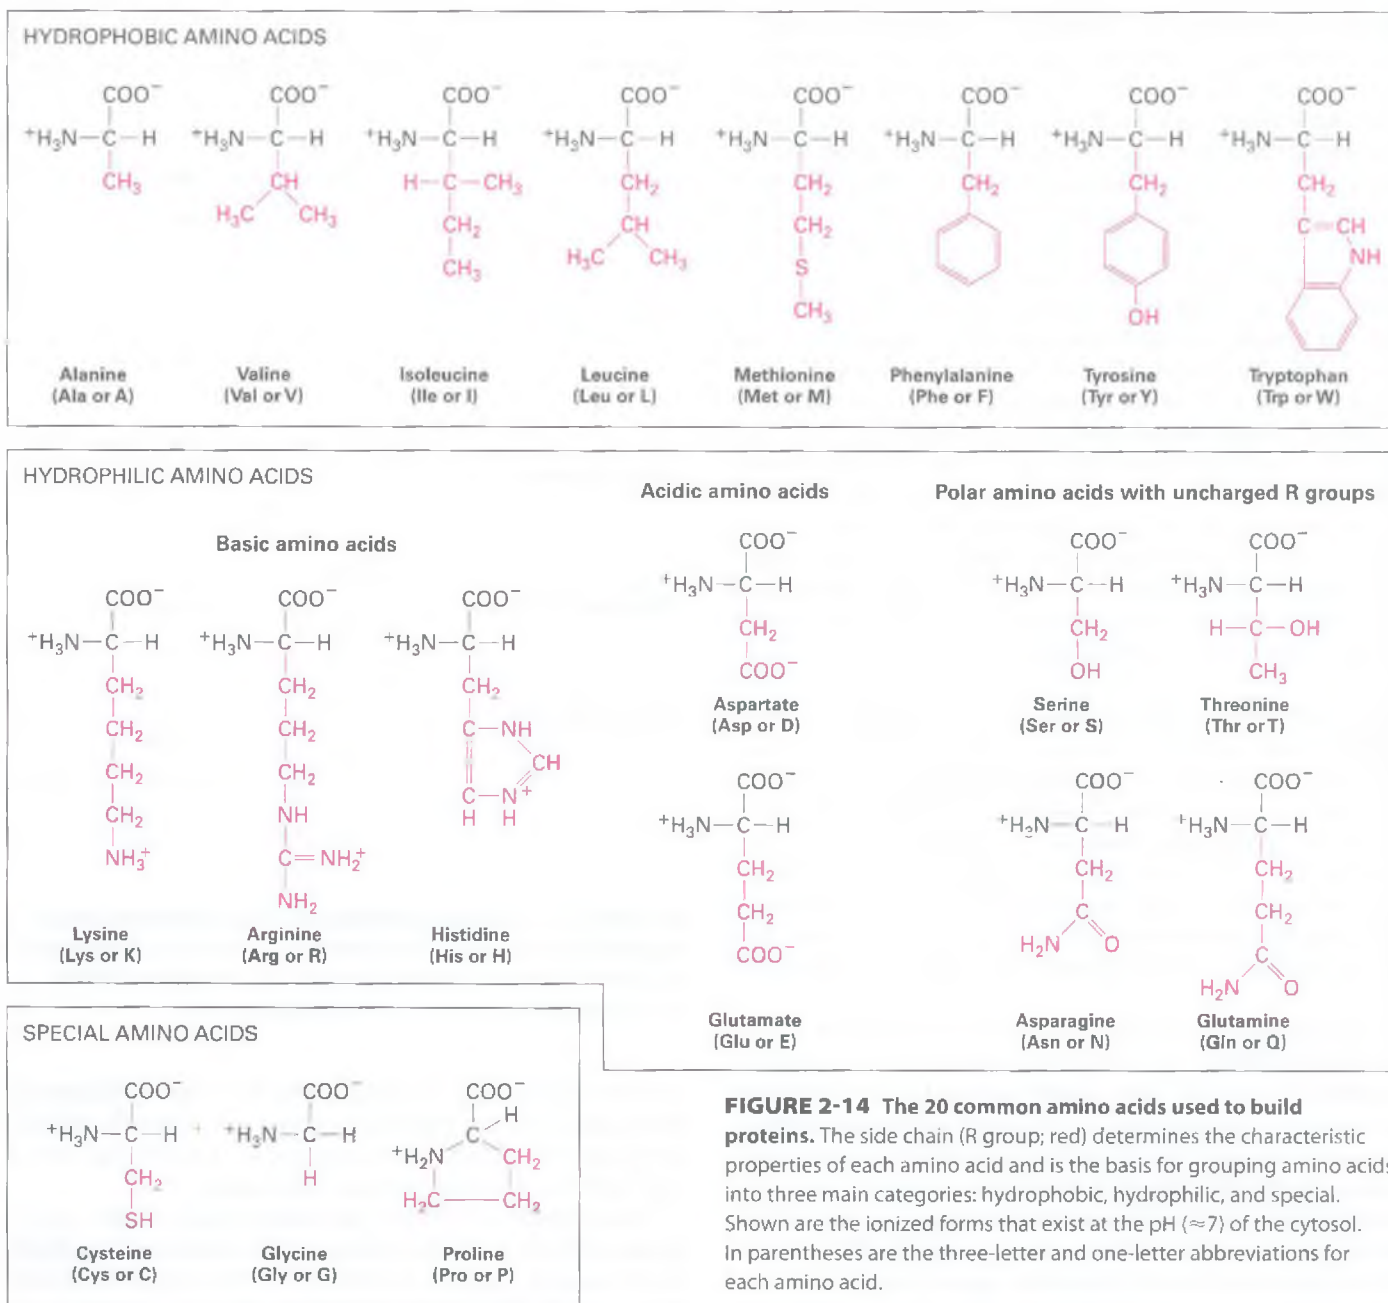

FIGURE 2-14 The 20 common amino acids used to build proteins. The side chain (R group; red) determines the characteristic properties of each amino acid and is the basis for grouping amino acids into three main categories: hydrophobic, hydrophilic, and special. Shown are the ionized forms that exist at the pH (≈ 7) of the cytosol. In parentheses are the three-letter and one-letter abbreviations for each amino acid.

groups with extensive hydrogen-bonding capacities. Similarly, *serine* and *threonine* are uncharged but have polar hydroxyl groups, which also participate in hydrogen bonds with other polar molecules.

Lastly, cysteine, glycine, and proline exhibit special roles in proteins because of the unique properties of their side chains. The side chain of *cysteine* contains a reactive *sulfhydryl group* ($-\text{SH}$). On release of a proton (H^+), a sulfhydryl is converted into a thiolate anion (S^-). Thiolate anions can play important roles in catalysis, notably in certain enzymes that destroy proteins (proteases). In proteins, each of two adjacent sulfhydryl groups can be oxidized, each releasing a proton and an electron, to form a covalent *disulfide bond* ($-\text{S}-\text{S}-$):

Disulfide bonds serve to “cross-link” regions within a single polypeptide chain (intramolecular) or between two separate chains (intermolecular). Disulfide bonds stabilize the folded structure of some proteins. The smallest amino acid, *glycine*, has a single hydrogen atom as its R group. Its small size allows it to fit into tight spaces. Unlike the other common amino acids, the side chain of *proline* (pronounced pro-leen) bends around to form a ring by covalently bonding to the nitrogen atom in the amino group attached to the C $_{\alpha}$. As a result, proline is very rigid and the amino group is not available for typical hydrogen bonding. The presence of proline in a protein creates a fixed kink in the polymer chain, limiting how it can fold in the region of the proline residue.

Some amino acids are more abundant in proteins than others. Cysteine, tryptophan, and methionine are not common amino acids; together they constitute approximately 5 percent of the amino acids in a typical protein. Four amino acids—leucine, serine, lysine, and glutamic acid—are the most abundant amino acids, totaling 32 percent of all the amino acid residues in a typical protein. However, the amino acid compositions of proteins can vary widely from these values.

 Humans and other mammals can synthesize 11 of the 20 amino acids. The other nine are called *essential amino acids* and must be included in the diet to permit normal protein production. These are phenylalanine, valine, threonine, tryptophan, isoleucine, methionine, leucine, lysine, and histidine. Adequate provision of these essential amino acids in feed is key to the livestock industry. Indeed, a genetically engineered corn with high lysine content is now in use as an “enhanced” feed to promote the growth of animals. ■

Although cells use the 20 amino acids shown in Figure 2-14 in the *initial* synthesis of proteins, analysis of cellular proteins reveals that they contain upward of 100 different amino acids. The difference is due to the chemical modifications of some of amino acids after they are incorporated into protein by the addition of acetyl groups (CH $_3$ CO) and a variety of other chemical groups (Figure 2-15). An important modification is the addition of a phosphate (PO $_4$) to hydroxyl groups in serine, threonine, and tyrosine residues, a process known as phosphorylation. We will encounter numerous examples of proteins whose activity is regulated by reversible phosphorylation and dephosphorylation. Phosphorylation of nitrogen in the side chain of histidine is well known in bacteria, fungi, and plants but less studied—perhaps because of the relative instability of phosphorylated histidine—and apparently rare in mammals. The side chains of asparagine, serine, and threonine are sites for glycosylation, the attachment of linear and branched carbohydrate chains. Many secreted proteins and membrane proteins contain glycosylated residues, and the reversible modification of hydroxyl groups on specific serines and threonines by a sugar called N-acetylglucosamine also regulates protein activities. Other amino acid modifications found in selected proteins include the hydroxylation of proline and lysine residues in collagen (see Chapter 19), the methylation of histidine

FIGURE 2-15 Common modifications of amino acid side chains in proteins. These modified residues and numerous others are formed by addition of various chemical groups (red) to the amino acid side chains during or after synthesis of a polypeptide chain.

residues in membrane receptors, and the γ carboxylation of glutamate in blood-clotting factors such as prothrombin. Deamidation of Asn and Gln to the corresponding acids, Asp and Glu, is also a common occurrence.

Acetylation, addition of an acetyl group, to the amino group of the N-terminal residue, is the most common form of amino acid chemical modification, affecting an estimated 80 percent of all proteins:

This modification may play an important role in controlling the life span of proteins within cells because many nonacetylated proteins are rapidly degraded.

Five Different Nucleotides Are Used to Build Nucleic Acids

Two types of chemically similar nucleic acids, DNA (deoxyribonucleic acid) and RNA (ribonucleic acid), are the principal

FIGURE 2-16 Common structure of nucleotides. (a) Adenosine 5'-monophosphate (AMP), a nucleotide present in RNA. By convention, the carbon atoms of the pentose sugar in nucleotides are numbered with primes. In natural nucleotides, the 1' carbon is joined by a β linkage to the base (in this case adenine); both the base (blue) and the phosphate (on the 5' hydroxyl (red)) extend above the plane of the sugar ring. (b) Ribose and deoxyribose, the pentoses in RNA and DNA, respectively.

genetic-information-carrying molecules of the cell. The monomers from which DNA and RNA polymers are built, called **nucleotides**, all have a common structure: a phosphate group linked by a phosphoester bond to a pentose (five-carbon) sugar that in turn is linked to a nitrogen- and carbon-containing ring structure commonly referred to as a base (Figure 2-16a). In RNA, the pentose is ribose; in DNA, it is deoxyribose that at position 2' has a proton rather than a hydroxyl group (Figure 2-16b). (We describe the structures of sugars in more detail below.) The bases *adenine*, *guanine*, and *cytosine* (Figure 2-17) are found in both DNA and RNA; *thymine* is found only in DNA, and *uracil* is found only in RNA.

Adenine and guanine are **purines**, which contain a pair of fused rings; cytosine, thymine, and uracil are **pyrimidines**, which contain a single ring (see Figure 2-17). The bases are often abbreviated A, G, C, T, and U, respectively; these same single-letter abbreviations are also commonly used to denote the entire nucleotides in nucleic acid polymers. In nucleotides, the 1' carbon atom of the sugar (ribose or deoxyribose) is attached to the nitrogen at position 9 of a purine (N_9) or at position 1 of a pyrimidine (N_1). The acidic character of nucleotides is due to the phosphate group, which under normal intracellular conditions releases hydrogen ions (H^+), leaving the phosphate negatively charged (see Figure 2-16a). Most nucleic acids in cells are associated with proteins, which form ionic interactions with the negatively charged phosphates.

Cells and extracellular fluids in organisms contain small concentrations of **nucleosides**, combinations of a base and a sugar without a phosphate. Nucleotides are nucleosides that have one, two, or three phosphate groups esterified at the 5' hydroxyl. Nucleoside monophosphates have a single esterified

FIGURE 2-17 Chemical structures of the principal bases in nucleic acids. In nucleic acids and nucleotides, nitrogen 9 of purines and nitrogen 1 of pyrimidines (red) are bonded to the 1' carbon of ribose or deoxyribose. U is only found in RNA, and T is only found in DNA. Both RNA and DNA contain A, G, and C.

phosphate (see Figure 2-16a); nucleoside diphosphates contain a pyrophosphate group:

and nucleoside triphosphates have a third phosphate. Table 2-3 lists the names of the nucleosides and nucleotides in nucleic acids and the various forms of nucleoside phosphates. The nucleoside triphosphates are used in the synthesis of nucleic acids, which we cover in Chapter 4. Among their other functions in the cell, GTP participates in intracellular signaling and acts as an energy reservoir, particularly in protein synthesis, and ATP, discussed later in this chapter, is the most widely used biological energy carrier.

Monosaccharides Covalently Assemble into Linear and Branched Polysaccharides

The building blocks of the polysaccharides are the simple sugars, or **monosaccharides**. Monosaccharides are **carbohydrates**, which are literally covalently bonded combinations of carbon and water in a one-to-one ratio $(CH_2O)_n$, where n equals 3, 4, 5, 6, or 7. **Hexoses** ($n = 6$) and **pentoses** ($n = 5$) are the most common monosaccharides. All monosaccharides

TABLE 2-3 Terminology of Nucleosides and Nucleotides

		Purines		Pyrimidines	
Bases		Adenine (A)	Guanine (G)	Cytosine (C)	Uracil (U) Thymine (T)
Nucleosides	in RNA	Adenosine	Guanosine	Cytidine	Uridine
	in DNA	Deoxyadenosine	Deoxyguanosine	Deoxycytidine	Deoxythymidine
Nucleotides	in RNA	Adenylate	Guanylate	Cytidylate	Uridylate
	in DNA	Deoxyadenylate	Deoxyguanylate	Deoxycytidylate	Deoxythymidylate
Nucleoside monophosphates		AMP	GMP	CMP	UMP
Nucleoside diphosphates		ADP	GDP	CDP	UDP
Nucleoside triphosphates		ATP	GTP	CTP	UTP
Deoxynucleoside mono-, di-, and triphosphates		dAMP, etc.	dGMP, etc.	dCMP, etc.	dTMP, etc.

contain hydroxyl (—OH) groups and either an aldehyde or a keto group:

Many biologically important sugars are hexoses, including glucose, mannose, and galactose (Figure 2-18). Mannose is identical to glucose except that the orientation of the groups bonded to carbon 2 is reversed. Similarly, galactose, another hexose, differs from glucose only in the orientation of the groups attached to carbon 4. Interconversion of glucose and mannose or galactose requires the breaking and making of covalent bonds; such reactions are carried out by enzymes called *epimerases*.

D-Glucose ($\text{C}_6\text{H}_{12}\text{O}_6$) is the principal external source of energy for most cells in complex multicellular organisms and can exist in three different forms: a linear structure and two different hemiacetal ring structures (Figure 2-18a). If the aldehyde group on carbon 1 combines with the hydroxyl group on carbon 5, the resulting hemiacetal, D-glucopyranose, contains a six-member ring. In the α anomer of D-glucopyranose, the hydroxyl group attached to carbon 1 points “downward” from the ring as shown in Figure 2-18a; in the β anomer, this hydroxyl points “upward.” In aqueous solution, the α and β anomers readily interconvert spontaneously; at equilibrium there is about one-third α anomer and two-thirds

FIGURE 2-18 Chemical structures of hexoses. All hexoses have the same chemical formula ($\text{C}_6\text{H}_{12}\text{O}_6$) and contain an aldehyde or a keto group. (a) The ring forms of D-Glucose are generated from the linear molecule by reaction of the aldehyde at carbon 1 with the hydroxyl on carbon 5 or carbon 4. The three forms are readily interconvertible, although the pyranose form (right) predominates in biological systems. (b) In D-mannose and D-galactose, the configuration of the H (green) and OH (blue) bound to one carbon atom differs from that in glucose. These sugars, like glucose, exist primarily as pyranoses (six-member rings).

β , with very little of the open-chain form. Because enzymes can distinguish between the α and β anomers of D-glucose, these forms have distinct biological roles. Condensation of the hydroxyl group on carbon 4 of the linear glucose with its aldehyde group results in the formation of D-glucofuranose, a hemiacetal containing a five-member ring. Although all three forms of D-glucose exist in biological systems, the pyranose (six-member ring) form is by far the most abundant.

The pyranose ring in Figure 2-18a is depicted as planar. In fact, because of the tetrahedral geometry around carbon atoms, the most stable conformation of a pyranose ring has a nonplanar, chairlike shape. In this conformation, each bond from a ring carbon to a nonring atom (e.g., H or O) is either nearly perpendicular to the ring, referred to as axial (a), or nearly in the plane of the ring, referred to as equatorial (e):

Disaccharides, formed from two monosaccharides, are the simplest polysaccharides. The disaccharide lactose, composed of galactose and glucose, is the major sugar in milk; the disaccharide sucrose, composed of glucose and fructose, is a principal product of plant photosynthesis and is refined into common table sugar (Figure 2-19).

Larger polysaccharides, containing dozens to hundreds of monosaccharide units, can function as reservoirs for glucose, as structural components, or as adhesives that help hold cells together in tissues. The most common storage carbohydrate in animal cells is **glycogen**, a very long, highly branched polymer of glucose. As much as 10 percent by weight of the liver can be glycogen. The primary storage carbohydrate in plant cells, **starch**, also is a glucose polymer. It occurs in an unbranched form (amylose) and lightly branched form (amylopectin).

Both glycogen and starch are composed of the α anomer of glucose. In contrast, **cellulose**, the major constituent of plant cell walls that confers stiffness to many plant structures (see Chapter 19), is an unbranched polymer of the β anomer of glucose. Human digestive enzymes can hydrolyze the α glycosidic bonds in starch but not the β glycosidic bonds in cellulose. Many species of plants, bacteria, and molds produce cellulose-degrading enzymes. Cows and termites can break down cellulose because they harbor cellulose-degrading bacteria in their gut. Bacterial cell walls consist of **peptidoglycan**, a polysaccharide chain cross-linked by peptide cross-bridges, which confers rigidity and cell shape. Human tear and gastrointestinal fluids contain lysozyme, an enzyme capable of hydrolyzing peptidoglycan in the bacterial cell wall.

The enzymes that make the glycosidic bonds linking monosaccharides into polysaccharides are specific for the α or β anomer of one sugar and a particular hydroxyl group on the other. In principle, any two sugar molecules can be linked in a variety of ways because each monosaccharide has multiple hydroxyl groups that can participate in the formation of glycosidic bonds. Furthermore, any one monosaccharide has the potential of being linked to more than two other monosaccharides, thus generating a branch point and nonlinear polymers. Glycosidic bonds are usually formed between the growing polysaccharide chain and a covalently modified form of a monosaccharide. Such modifications include a phosphate (e.g., glucose 6-phosphate) or a nucleotide (e.g., UDP-galactose):

The epimerase enzymes that interconvert different monosaccharides often do so using the nucleotide sugars rather than the unsubstituted sugars.

FIGURE 2-19 Formation of the disaccharides lactose and sucrose. In any glycosidic linkage, the anomeric carbon of one sugar molecule (in either the α or β conformation) is linked to a hydroxyl oxygen on another sugar molecule. The linkages are named accordingly; thus lactose contains a $\beta(1 \rightarrow 4)$ bond, and sucrose contains an $\alpha(1 \rightarrow 2)$ bond.

FIGURE 2-20 Phosphatidylcholine, a typical phosphoglyceride.

All phosphoglycerides are amphipathic phospholipids, having a hydrophobic tail (yellow) and a hydrophilic head (blue) in which glycerol is linked via a phosphate group to an alcohol. Either or both

of the fatty acyl side chains in a phosphoglyceride may be saturated or unsaturated. In phosphatidic acid (red), the simplest phospholipid, the phosphate is not linked to an alcohol.

Many complex polysaccharides contain modified sugars that are covalently linked to various small groups, particularly amino, sulfate, and acetyl groups. Such modifications are abundant in **glycosaminoglycans**, major polysaccharide components of the extracellular matrix that we describe in Chapter 19.

Phospholipids Associate Noncovalently to Form the Basic Bilayer Structure of Biomembranes

Biomembranes are large, flexible sheets with a two-ply, or bilayer, structure that serve as the boundaries of cells and their intracellular organelles and form the outer surfaces of some viruses. Membranes literally define what is a cell (the outer membrane and the contents within the membrane) and what is not (the extracellular space outside the membrane). Unlike proteins, nucleic acids, and polysaccharides, membranes are assembled by the *noncovalent* association of their component building blocks. The primary building blocks of all biomembranes are **phospholipids**, whose physical properties are responsible for the formation of the sheet-like bilayer structure of membranes. In addition to phospholipids, biomembranes can contain a variety of other molecules, including cholesterol, glycolipids, and proteins. The structure and functions of biomembranes will be described in detail in Chapter 10. Here we will focus on the phospholipids in biomembranes.

To understand the structure of phospholipids, we have to understand each of their component parts and how they are assembled. Phospholipids consist of two long-chain, nonpolar fatty acid groups linked (usually by an ester bond) to small, highly polar groups, including a phosphate and a short organic molecule, such as glycerol (trihydroxy propanol) (Figure 2-20).

Fatty acids consist of a hydrocarbon (acyl) chain attached to a carboxyl group (—COOH). Like glucose, fatty acids are an important energy source for many cells (see Chapter 12). They differ in length, although the predominant fatty acids in cells have an even number of carbon atoms, usually 14, 16, 18, or 20. The major fatty acids in

phospholipids are listed in Table 2-4. Fatty acids often are designated by the abbreviation Cx:y , where x is the number of carbons in the chain and y is the number of double bonds. Fatty acids containing 12 or more carbon atoms are nearly insoluble in aqueous solutions because of their long hydrophobic hydrocarbon chains.

Fatty acids in which all the carbon-carbon bonds are single bonds, that is, the fatty acids have no carbon-carbon double bonds, are said to be **saturated**; those with at least one carbon-carbon double bond are called **unsaturated**. Unsaturated fatty acids with more than one carbon-carbon double bond are referred to as **polyunsaturated**. Two “essential” polyunsaturated fatty acids, linoleic acid ($\text{C}_{18:2}$) and linolenic acid ($\text{C}_{18:3}$), cannot be synthesized by mammals and must be supplied in their diet. Mammals can synthesize other common fatty acids.

In phospholipids, fatty acids are covalently attached to another molecule by a type of dehydration reaction called *esterification*, in which the OH from the carboxyl group of the fatty acid and an H from a hydroxyl group on the other molecule are lost. In the combined molecule formed by this reaction, the part derived from the fatty acid is called an *acyl group*, or *fatty acyl group*. This is illustrated by the most common forms of phospholipids: **phosphoglycerides**, which contain two acyl groups attached to two of the hydroxyl groups of glycerol (see Figure 2-20).

In phosphoglycerides, one hydroxyl group of the glycerol is esterified to phosphate while the other two normally are esterified to fatty acids. The simplest phospholipid, phosphatidic acid, contains only these components. Phospholipids such as phosphatidic acid are not only membrane building blocks but are also important signaling molecules. **Lyso-phosphatidic acid**, in which the acyl chain at the 2 position has been removed, is relatively water soluble and can be a potent inducer of cell division (called a mitogen). In most phospholipids found in membranes, the phosphate group is also esterified to a hydroxyl group on another hydrophilic compound. In phosphatidylcholine, for example, choline is attached to the phosphate (see Figure 2-20). The negative charge on the phosphate as well as the charged or polar groups esterified to it can interact strongly with water. The

TABLE 2-4 Fatty Acids That Predominate in Phospholipids

Common Name of Acid (ionized form in parentheses)	Abbreviation	Chemical Formula
Saturated Fatty Acids		
Myristic (myristate)	C14:0	$\text{CH}_3(\text{CH}_2)_{12}\text{COOH}$
Palmitic (palmitate)	C16:0	$\text{CH}_3(\text{CH}_2)_{14}\text{COOH}$
Stearic (stearate)	C18:0	$\text{CH}_3(\text{CH}_2)_{16}\text{COOH}$
Unsaturated Fatty Acids		
Oleic (oleate)	C18:1	$\text{CH}_3(\text{CH}_2)_7\text{CH}=\text{CH}(\text{CH}_2)_7\text{COOH}$
Linoleic (linoleate)	C18:2	$\text{CH}_3(\text{CH}_2)_4\text{CH}=\text{CHCH}_2\text{CH}=\text{CH}(\text{CH}_2)_7\text{COOH}$
Arachidonic (arachidonate)	C20:4	$\text{CH}_3(\text{CH}_2)_4(\text{CH}=\text{CHCH}_2)_3\text{CH}=\text{CH}(\text{CH}_2)_3\text{COOH}$

phosphate and its associated esterified group, the “head” group of a phospholipid, is hydrophilic, whereas the fatty acyl chains, the “tails,” are hydrophobic. Other common phosphoglycerides and associated head groups are shown in Table 2-5. Molecules such as phospholipids that have both

hydrophobic and hydrophilic regions are called amphipathic. In Chapter 10, we will see how the amphipathic properties of phospholipids are responsible for the assembly of phospholipids into sheet-like bilayer biomembranes in which the fatty acyl tails point into the center of the sheet and the head groups point outward toward the aqueous environment (see Figure 2-13).

Fatty acyl groups also can be covalently linked into other fatty molecules, including triacylglycerols, or triglycerides, which contain three acyl groups esterified to glycerol:

TABLE 2-5 Common Phosphoglycerides and Head Groups

Common Phosphoglycerides	Head Group
Phosphatidylcholine	 Choline
Phosphatidylethanolamine	 Ethanolamine
Phosphatidylserine	 Serine
Phosphatidylinositol	 Inositol

and covalently attached to the very hydrophobic molecule cholesterol, an alcohol, to form cholesteryl esters:

Triglycerides and cholesteryl esters are extremely water-insoluble molecules in which fatty acids and cholesterol are either stored or transported. Triglycerides are the storage form of fatty acids in the fat cells of adipose tissue and are the principal components of dietary fats. Cholesteryl esters and triglycerides are transported between tissues through the bloodstream in specialized carriers called lipoproteins (see Chapter 14).

 We saw above that the fatty acids making up phospholipids (both phosphoglycerides and triglycerides) can be either saturated or unsaturated. An important consequence of the carbon-carbon double bond ($C=C$) in an unsaturated fatty acid is that two stereoisomeric configurations, *cis* and *trans*, are possible around each of these bonds:

a *cis* double bond introduces a rigid kink in the otherwise flexible straight acyl chain of a saturated fatty acid (Figure 2-21). In general, the unsaturated fatty acids in biological systems contain only *cis* double bonds. Saturated fatty acids without the kink can pack together tightly and so have higher melting points than unsaturated fatty acids. The main fatty molecules in butter are triglycerides with saturated fatty acyl chains, which is why butter is usually solid at room temperature.

FIGURE 2-21 The effect of a double bond on the shape of fatty acids. Shown are chemical structures of the ionized form of palmitic acid, a saturated fatty acid with 16 C atoms, and oleic acid, an unsaturated one with 18 C atoms. In saturated fatty acids, the

unsaturated fatty acids or fatty acyl chains with the *cis* double bond kink cannot pack as closely together as saturated fatty acyl chains. Thus, vegetable oils, composed of triglycerides with unsaturated fatty acyl groups, usually are liquid at room temperature. Vegetable and similar oils are partially hydrogenated to convert some of their unsaturated fatty acyl chains to saturated fatty acyl chains. As a consequence, the hydrogenated vegetable oil can be molded into solid sticks of margarine. A by-product of the hydrogenation reaction is the conversion of some of the fatty acyl chains into *trans* fatty acids, popularly called “*trans* fats.” The “*trans* fats,” found in partially hydrogenated margarine and other food products, are not natural. Saturated and *trans* fatty acids have similar physical properties; for example, they tend to be solids at room temperature. Their consumption, relative to the consumption of unsaturated fats, is associated with increased plasma cholesterol levels and is discouraged by some nutritionists. ■

KEY CONCEPTS of Section 2.2

Chemical Building Blocks of Cells

- Macromolecules are polymers of monomer subunits linked together by covalent bonds via dehydration reactions. Three major types of macromolecules are found in cells: proteins, composed of amino acids linked by peptide bonds; nucleic acids, composed of nucleotides linked by phosphodiester

hydrocarbon chain is often linear; the *cis* double bond in oleate creates a rigid kink in the hydrocarbon chain. [After L. Stryer, 1994, *Biochemistry*, 4th ed., W. H. Freeman and Company, p. 265.]

bonds; and polysaccharides, composed of monosaccharides (sugars) linked by glycosidic bonds (see Figure 2-13). Phospholipids, the fourth major chemical building block, assemble noncovalently into biomembranes.

- Differences in the size, shape, charge, hydrophobicity, and reactivity of the side chains of the 20 common amino acids determine the chemical and structural properties of proteins (see Figure 2-14).

- The bases in the nucleotides composing DNA and RNA are carbon- and nitrogen-containing rings attached to a pentose sugar. They form two groups: the purines—adenine (A) and guanine (G)—and the pyrimidines—cytosine (C), thymine (T), and uracil (U) (see Figure 2-17). A, G, T, and C are found in DNA, and A, G, U, and C are found in RNA.

- Glucose and other hexoses can exist in three forms: an open-chain linear structure, a six-member (pyranose) ring, and a five-member (furanose) ring (see Figure 2-18). In biological systems, the pyranose form of D-glucose predominates.

- Glycosidic bonds are formed between either the α or the β anomer of one sugar and a hydroxyl group on another sugar, leading to formation of disaccharides and other polysaccharides (see Figure 2-19).

- Phospholipids are amphipathic molecules with a hydrophobic tail (often two fatty acyl chains) connected by a small organic molecule (often glycerol) to a hydrophilic head (see Figure 2-20).

- The long hydrocarbon chain of a fatty acid may be saturated (containing no carbon-carbon double bond) or unsaturated (containing one or more double bonds). Fatty substances such as butter that have primarily saturated fatty acyl chains tend to be solid at room temperature, whereas unsaturated fats with *cis* double bonds have kinked chains that cannot pack closely together and so tend to be liquids at room temperature.

2.3 Chemical Reactions and Chemical Equilibrium

We now shift our discussion to chemical reactions in which bonds, primarily covalent bonds in *reactant* chemicals, are broken and new bonds are formed to generate reaction *products*. At any one time, several hundred different kinds of chemical reactions are occurring simultaneously in every cell, and many chemicals can, in principle, undergo multiple chemical reactions. Both the *extent* to which reactions can proceed and the *rate* at which they take place determine the chemical composition of cells. In this section, we discuss the concepts of equilibrium and steady state as well as dissociation constants and pH. In Section 2.4, we discuss how energy influences the extents and rates of chemical reactions.

FIGURE 2-22 Time dependence of the rates of a chemical reaction. The forward and reverse rates of a reaction depend in part on the initial concentrations of reactants and products. The net forward reaction rate slows as the concentration of reactants decreases, whereas the net reverse reaction rate increases as the concentration of products increases. At equilibrium, the rates of the forward and reverse reactions are equal and the concentrations of reactants and products remain constant.

A Chemical Reaction Is in Equilibrium When the Rates of the Forward and Reverse Reactions Are Equal

When reactants first mix together—before any products have been formed—the rate of the forward reaction to form products is determined in part by their initial concentrations, which determine the likelihood of reactants bumping into one another and reacting (Figure 2-22). As the reaction products accumulate, the concentration of each reactant decreases and so does the forward reaction rate. Meanwhile, some of the product molecules begin to participate in the reverse reaction, which re-forms the reactants. The ability of a reaction to go “backward” is called *microscopic reversibility*. The reverse reaction is slow at first but speeds up as the concentration of product increases. Eventually, the rates of the forward and reverse reactions become equal, so that the concentrations of reactants and products stop changing. The system is then said to be in **chemical equilibrium** (plural: *equilibria*).

The ratio of the concentrations of the products to reactants when they reach equilibrium, called the **equilibrium constant**, K_{eq} , is a fixed value. Thus K_{eq} provides a measure of the extent to which a reaction occurs by the time it reaches equilibrium. The rate of a chemical reaction can be increased by a **catalyst**, but a catalyst does not change the equilibrium constant (see Section 2.4). A catalyst accelerates the making and breaking of covalent bonds but itself is not permanently changed during a reaction.

The Equilibrium Constant Reflects the Extent of a Chemical Reaction

For any chemical reaction, K_{eq} depends on the nature of the reactants and products, the temperature, and the pressure (particularly in reactions involving gases). Under standard physical conditions (25 °C and 1 atm pressure for biological systems), the K_{eq} is always the same for a given reaction, whether or not a catalyst is present.

For the general reaction with three reactants and three products

where capital letters represent particular molecules or atoms and lowercase letters represent the number of each in the reaction formula; the equilibrium constant is given by

$$K_{eq} = \frac{[X]^x[Y]^y[Z]^z}{[A]^a[B]^b[C]^c} \quad (2-2)$$

where brackets denote the concentrations of the molecules at equilibrium. The rate of the forward reaction (left to right in Equation 2-1) is

$$\text{Rate}_{\text{forward}} = k_f[A]^a[B]^b[C]^c$$

where k_f is the **rate constant** for the forward reaction. Similarly, the rate of the reverse reaction (right to left in Equation 2-1) is

$$\text{Rate}_{\text{reverse}} = k_r[X]^x[Y]^y[Z]^z$$

where k_r is the rate constant for the reverse reaction. It is important to remember that the forward and reverse rates of a reaction can change because of changes in reactant or product concentrations, yet at the same time the forward and reverse rate constants do not change; hence the name “constant.” Confusing rates and rate constants is a common error. At equilibrium the forward and reverse rates are equal, so $\text{Rate}_{\text{forward}}/\text{Rate}_{\text{reverse}} = 1$. By rearranging these equations, we can express the equilibrium constant as the ratio of the rate constants:

$$K_{eq} = \frac{k_f}{k_r} \quad (2-3)$$

The concept of K_{eq} is particularly helpful when we want to think about the energy that is released or absorbed when a chemical reaction occurs. We will discuss this in considerable detail in Section 2.4.

Chemical Reactions in Cells Are at Steady State

Under appropriate conditions and given sufficient time, a single biochemical reaction carried out in a test tube eventually will reach equilibrium and the concentration of reactants and products does not change with time because the rates of the forward and reverse reactions are equal. Within cells, however, many reactions are linked in pathways in which a product of one reaction has alternative fates to simply reconverting via a reverse reaction to the reactants and thus ultimately reaching equilibrium. For example, the product of one reaction might serve as a reactant in another, or it might be

(a) Test tube equilibrium concentrations

(b) Intracellular steady-state concentrations

FIGURE 2-23 Comparison of reactions at equilibrium and steady state.

(a) In the test tube, a biochemical reaction ($A \rightarrow B$) eventually will reach equilibrium, in which the rates of the forward and reverse reactions are equal (as indicated by the reaction arrows of equal length). (b) In metabolic pathways within cells, the product B commonly would be consumed, in this example by conversion to C. A pathway of linked reactions is at steady state when the rate of formation of the intermediates (e.g., B) equals their rate of consumption. As indicated by the unequal length of the arrows, the individual reversible reactions constituting a metabolic pathway do not reach equilibrium. Moreover, the concentrations of the intermediates at steady state can differ from what they would be at equilibrium.

pumped out of the cell. In this more complex situation, the original reaction can never reach equilibrium because some of the products do not have a chance to be converted back to reactants. Nevertheless, in such non-equilibrium conditions the rate of formation of a substance can be equal to the rate of its consumption, and as a consequence the concentration of the substance remains constant over time. In such circumstances, the system of linked reactions for producing and consuming that substance is said to be in a **steady state** (Figure 2-23). One consequence of such linked reactions is that they prevent the accumulation of excess intermediates, protecting cells from the harmful effects of intermediates that are toxic at high concentrations. When the concentration of a product of an ongoing reaction is not changing over time, it might be a consequence of a state of equilibrium or it might be a consequence of a steady state. In biological systems when metabolite concentrations, such as blood glucose levels, are not changing with time—a condition called *homeostasis*—it is a consequence of a steady state rather than equilibrium.

Dissociation Constants of Binding Reactions Reflect the Affinity of Interacting Molecules

The concept of equilibrium also applies to the binding of one molecule to another. Many important cellular processes depend on such binding “reactions,” which involve the making and breaking of various noncovalent interactions rather than covalent bonds, as discussed above. A common example is the binding of a **ligand** (e.g., the hormone insulin or adrenaline) to its **receptor** on the surface of a cell, which triggers an intracellular signaling pathway (see Chapter 15). Another example is the binding of a protein to a specific sequence of base pairs in a molecule of DNA, which frequently causes the expression of a nearby gene to increase or decrease (see Chapter 7). If the equilibrium constant for a binding reaction is known, the stability of the resulting complex can be

FIGURE 2-24 Macromolecules can have distinct binding sites for multiple ligands. A large macromolecule (e.g., a protein, blue) with three distinct binding sites (A–C) is shown; each binding site exhibits molecular complementarity to three different binding partners (ligands A–C) with distinct dissociation constants (K_{dA-C}).

predicted. To illustrate the general approach for determining the concentration of noncovalently associated complexes, we will calculate the extent to which a protein (P) is bound to DNA (D), forming a protein-DNA complex (PD):

Most commonly, binding reactions are described in terms of the **dissociation constant** K_d , which is the reciprocal of the equilibrium constant. For this binding reaction, the dissociation constant is given by

$$K_d = \frac{[P][D]}{[PD]} \quad (2-4)$$

It is worth noting that in such a binding reaction, when half of the DNA is bound to the protein ($[PD] = [D]$), the concentration of P is equal to the K_d . The lower the K_d , the lower the concentration of P needed to bind to half of D. In other words, the lower the K_d , the tighter the binding (the higher the affinity) of P for D. Typical reactions in which a protein binds to a specific DNA sequence have a K_d of 10^{-10} M, where M symbolizes molarity, or moles per liter (mol/L). To relate the magnitude of this dissociation constant to the intracellular ratio of bound to unbound DNA, let's consider the simple example of a bacterial cell having a volume of 1.5×10^{-15} L and containing 1 molecule of DNA and 10 molecules of the DNA-binding protein P. In this case, given a K_d of 10^{-10} M and the total concentration of the P in the cell ($\sim 111 \times 10^{-10}$ M, 100-fold higher than the K_d), 99 percent of the time this specific DNA sequence will have a molecule of protein bound to it and 1 percent of the time it will not, even though the cell contains only 10 molecules of the protein! Clearly, P and D have a high affinity for each other and bind tightly, as reflected by the low value of the dissociation constant for their binding reaction. For protein-protein and protein-DNA binding, K_d values of $\leq 10^{-9}$ M (nanomolar) are considered to be tight, $\sim 10^{-6}$ M (micromolar) modestly tight, and $\sim 10^{-3}$ M (millimolar) relatively weak.

A large biological macromolecule, such as a protein, can have multiple binding surfaces for binding several molecules simultaneously (Figure 2-24). In some cases, these binding reactions are independent, with their own distinct K_d values that are constant. In other cases, binding of a molecule at one site on a macromolecule can change the three-dimensional shape of a distant site, thus altering the binding interactions of that distant site with some other molecule. This is an important mechanism by which one molecule can alter, and thus regulate, the binding activity of another. We examine this regulatory mechanism in more detail in Chapter 3.

Biological Fluids Have Characteristic pH Values

The solvent inside cells and in all extracellular fluids is water. An important characteristic of any aqueous solution is the concentration of positively charged hydrogen ions (H^+) and negatively charged hydroxyl ions (OH^-). Because these ions are the dissociation products of H_2O , they are constituents of all living systems, and they are liberated by many reactions that take place between organic molecules within cells. These ions also can be transported into or out of cells, as when highly acidic gastric juice is secreted by cells lining the walls of the stomach.

When a water molecule dissociates, one of its polar $H-O$ bonds breaks. The resulting hydrogen ion, often referred to as a **proton**, has a short lifetime as a free ion and quickly combines with a water molecule to form a hydronium ion (H_3O^+). For convenience, we refer to the concentration of hydrogen ions in a solution, $[H^+]$, even though this really represents the concentration of hydronium ions, $[H_3O^+]$. Dissociation of H_2O generates one OH^- ion along with each H^+ . The dissociation of water is a reversible reaction:

At 25 °C, $[H^+][OH^-] = 10^{-14} M^2$, so that in pure water, $[H^+] = [OH^-] = 10^{-7} M$.

The concentration of hydrogen ions in a solution is expressed conventionally as its **pH**, defined as the negative log of the hydrogen ion concentration. The pH of pure water at 25 °C is 7:

$$pH = -\log[H^+] = \log \frac{1}{[H^+]} = \log \frac{1}{10^{-7}} = 7$$

It is important to keep in mind that a 1 unit difference in pH represents a tenfold difference in the concentration of protons. On the pH scale, 7.0 is considered neutral: pH values

FIGURE 2-25 pH values of common solutions. The pH of an aqueous solution is the negative log of the hydrogen ion concentration. The pH values for most intracellular and extracellular biological fluids are near 7 and are carefully regulated to permit the proper functioning of cells, organelles, and cellular secretions.

below 7.0 indicate acidic solutions (higher $[H^+]$), and values above 7.0 indicate basic, or alkaline, solutions (Figure 2-25). For instance, gastric juice, which is rich in hydrochloric acid (HCl), has a pH of about 1. Its $[H^+]$ is roughly a millionfold greater than that of cytoplasm, with a pH of about 7.2.

Although the cytosol of cells normally has a pH of about 7.2, the interior of certain organelles in eukaryotic cells (see Chapter 9) can have a much lower pH. Lysosomes, for example, have a pH of about 4.5. The many degradative enzymes within lysosomes function optimally in an acidic environment, whereas their action is inhibited in the near neutral environment of the cytoplasm. As this example illustrates, maintenance of a specific pH is essential for proper functioning of some cellular structures. On the other hand, dramatic shifts in cellular pH may play an important role in controlling cellular activity. For example, the pH of the cytoplasm of an unfertilized egg of the sea urchin, an aquatic animal, is 6.6. Within 1 minute of fertilization, however, the pH rises to 7.2; that is, the $[H^+]$ decreases to about one-fourth its original value, a change necessary for subsequent growth and division of the egg.

Hydrogen Ions Are Released by Acids and Taken Up by Bases

In general, an acid is any molecule, ion, or chemical group that tends to release a hydrogen ion (H^+), such as hydrochloric acid (HCl) or the carboxyl group ($-COOH$), which tends to dissociate to form the negatively charged carboxylate ion ($-COO^-$). Likewise, a base is any molecule, ion, or chemical group that readily combines with a H^+ , such as the hydroxyl ion (OH^-); ammonia (NH_3), which forms an ammonium ion (NH_4^+); or the amino group ($-NH_2$).

When acid is added to an aqueous solution, the $[H^+]$ increases and the pH goes down. Conversely, when a base is added to a solution, the $[H^+]$ decreases and the pH goes up. Because $[H^+][OH^-] = 10^{-14} M^2$, any increase in $[H^+]$ is coupled with a commensurate decrease in $[OH^-]$ and vice versa.

Many biological molecules contain both acidic and basic groups. For example, in neutral solutions (pH = 7.0), many amino acids exist predominantly in the doubly ionized form, in which the carboxyl group has lost a proton and the amino group has accepted one:

where R represents the uncharged side chain. Such a molecule, containing an equal number of positive and negative ions, is called a *zwitterion*. Zwitterions, having no net charge, are neutral. At extreme pH values, only one of these two ionizable groups of an amino acid will be charged.

The dissociation reaction for an acid (or acid group in a larger molecule) HA can be written as $HA \rightleftharpoons H^+ + A^-$. The equilibrium constant for this reaction, denoted K_a (the subscript *a* stands for “acid”), is defined as $K_a = [H^+][A^-]/[HA]$. Taking the logarithm of both sides and rearranging the result yields a very useful relation between the equilibrium constant and pH:

$$pH = pK_a + \log \frac{[A^-]}{[HA]} \quad (2-5)$$

where pK_a equals $-\log K_a$.

From this expression, commonly known as the *Henderson-Hasselbalch equation*, it can be seen that the pK_a of any acid is equal to the pH at which half the molecules are dissociated and half are neutral (undissociated). This is because when $[A^-] = [HA]$, then $\log ([A^-]/[HA]) = 0$, and thus $pK_a = pH$. The Henderson-Hasselbalch equation allows us to calculate the degree of dissociation of an acid if both the pH of the solution and the pK_a of the acid are known. Experimentally, by measuring the $[A^-]$ and $[HA]$ as a function of the solution's pH, one can calculate the pK_a of the acid and thus the equilibrium constant K_a for the dissociation reaction (Figure 2-26). Knowing the pK_a of a molecule not only provides an important description of its properties but

FIGURE 2-26 The relationship between pH, pK_a , and the dissociation of an acid. As the pH of a solution of carbonic acid rises from 0 to 8.5, the percentage of the compound in the undissociated, or non-ionized, form (H_2CO_3) decreases from 100 percent and that of the ionized form increases from 0 percent. When the pH (6.4) is equal to the acid's pK_a , half of the carbonic acid has ionized. When the pH rises to above 8, virtually all of the acid has ionized to the bicarbonate form (HCO_3^-).

also allows us to exploit these properties to manipulate the acidity of an aqueous solution and to understand how biological systems control this critical characteristic of their aqueous fluids.

Buffers Maintain the pH of Intracellular and Extracellular Fluids

A living, actively metabolizing cell must maintain a constant pH in the cytoplasm of about 7.2–7.4 despite the metabolic production of many acids, such as lactic acid and carbon dioxide; the latter reacts with water to form carbonic acid (H_2CO_3). Cells have a reservoir of weak bases and weak acids, called **buffers**, which ensure that the cell's cytoplasmic pH remains relatively constant despite small fluctuations in the amounts of H^+ or OH^- being generated by metabolism or by the uptake or secretion of molecules and ions by the cell. Buffers do this by “soaking up” excess H^+ or OH^- when these ions are added to the cell or are produced by metabolism.

If additional acid (or base) is added to a buffered solution whose pH is equal to the pK_a of the buffer ($[HA] = [A^-]$), the pH of the solution changes, but it changes less than it would if the buffer had not been present. This is because protons released by the added acid are taken up by the ionized form of the buffer (A^-); likewise, hydroxyl ions generated by the addition of base are neutralized by protons released by the undissociated buffer (HA). The capacity of a substance to release hydrogen ions or take them up depends partly on the extent to which the substance has already taken up or released protons, which in turn depends on the pH of the solution relative to the pK_a of the substance. The ability of a buffer to minimize changes in pH, its **buffering capacity**,

FIGURE 2-27 The titration curve of the buffer acetic acid (CH_3COOH). The pK_a for the dissociation of acetic acid to hydrogen and acetate ions is 4.75. At this pH, half the acid molecules are dissociated. Because pH is measured on a logarithmic scale, the solution changes from 91 percent CH_3COOH at pH 3.75 to 9 percent CH_3COOH at pH 5.75. The acid has maximum buffering capacity in this pH range.

depends on the concentration of the buffer and the relationship between its pK_a value and the pH, which is expressed by the Henderson-Hasselbalch equation.

The titration curve for acetic acid shown in Figure 2-27 illustrates the effect of pH on the fraction of molecules in the un-ionized (HA) and ionized forms (A^-). At one pH unit below the pK_a of an acid, 91 percent of the molecules are in the HA form; at one pH unit above the pK_a , 91 percent are in the A^- form. At pH values more than one unit above or below the pK_a , the buffering capacity of weak acids and bases declines rapidly. In other words, the addition of the same number of moles of acid to a solution containing a mixture of HA and A^- that is at a pH near the pK_a will cause less of a pH change than it would if the HA and A^- were not present or if the pH were far from the pK_a value.

All biological systems contain one or more buffers. Phosphate ions, the ionized forms of phosphoric acid, are present in considerable quantities in cells and are an important factor in maintaining, or buffering, the pH of the cytoplasm. Phosphoric acid (H_3PO_4) has three protons that are capable of dissociating, but they do not dissociate simultaneously. Loss of each proton can be described by a discrete dissociation reaction and pK_a , as shown in Figure 2-28. The titration curve for phosphoric acid shows that the pK_a for the dissociation of the second proton is 7.2. Thus at pH 7.2, about 50 percent of cellular phosphate is $H_2PO_4^-$ and about 50 percent is HPO_4^{2-} according to the Henderson-Hasselbalch equation. For this reason, phosphate is an excellent buffer at pH values around 7.2, the approximate pH of the cytoplasm of cells, and at pH 7.4, the pH of human blood.

FIGURE 2-28 The titration curve of phosphoric acid (H_3PO_4), a common buffer in biological systems. This biologically ubiquitous molecule has three hydrogen atoms that dissociate at different pH values; thus phosphoric acid has three pK_a values, as noted on the graph. The shaded areas denote the pH ranges—within one pH unit of the three pK_a values—where the buffering capacity of phosphoric acid is high. In these regions, the addition of acid (or base) will cause relatively small changes in the pH.

KEY CONCEPTS of Section 2.3

Chemical Reactions and Chemical Equilibrium

- A chemical reaction is at equilibrium when the rate of the forward reaction is equal to the rate of the reverse reaction, and thus there is no net change in the concentration of the reactants or products.
- The equilibrium constant K_{eq} of a reaction reflects the ratio of products to reactants at equilibrium and thus is a measure of the extent of the reaction and the relative stabilities of the reactants and products.
- The K_{eq} depends on the temperature, pressure, and chemical properties of the reactants and products but is independent of the reaction rate and of the initial concentrations of reactants and products.
- For any reaction, the equilibrium constant K_{eq} equals the ratio of the forward rate constant to the reverse rate constant (k_f/k_r). The rates of conversion of reactants to products and vice versa depend on the rate constants and the concentrations of the reactants or products.
- Within cells, the linked reactions in metabolic pathways generally are at steady state, not equilibrium, at which rate of formation of the intermediates equals their rate of consumption (see Figure 2-23) and thus the concentrations of the intermediates are not changing.
- The dissociation constant K_d for the noncovalent binding of two molecules is a measure of the stability of the complex

formed between the molecules (e.g., ligand-receptor or protein-DNA complexes).

- The pH is the negative logarithm of the concentration of hydrogen ions ($-\log [\text{H}^+]$). The pH of the cytoplasm is normally about 7.2–7.4, whereas the interior of lysosomes has a pH of about 4.5.
- Acids release protons (H^+), and bases bind them. In biological molecules, the carboxyl ($-\text{COOH}$) and phosphoryl groups ($-\text{H}_2\text{PO}_4$) are the most common acidic groups; the amino group ($-\text{NH}_2$) is the most common basic group.
- Buffers are mixtures of a weak acid (HA) and its corresponding base form (A^-), which minimize the change in pH of a solution when acid or base is added. Biological systems use various buffers to maintain their pH within a very narrow range.

2.4 Biochemical Energetics

The transformation of energy, its storage, and its use are central to the economy of the cell. Energy may be defined as the ability to do work, a concept as applicable to cells as to automobile engines and electric power plants. The energy stored within chemical bonds can be harnessed to support chemical work and the physical movements of cells. In this section, we will review how energy influences the extents of chemical reactions, a discipline called chemical thermodynamics, and the rates of chemical reactions, a discipline called chemical kinetics.

Several Forms of Energy Are Important in Biological Systems

There are two principal forms of energy: kinetic and potential. **Kinetic energy** is the energy of movement—the motion of molecules, for example. **Potential energy** is stored energy—the energy stored in covalent bonds, for example. Potential energy plays a particularly important role in the energy economy of cells.

Thermal energy, or heat, is a form of kinetic energy—the energy of the motion of molecules. For heat to do work, it must flow from a region of higher temperature—where the average speed of molecular motion is greater—to one of lower temperature. Although differences in temperature can exist between the internal and external environments of cells, these thermal gradients do not usually serve as the source of energy for cellular activities. The thermal energy in warm-blooded animals, which have evolved a mechanism for thermoregulation, is used chiefly to maintain constant organismic temperatures. This is an important homeostatic function because the rates of many cellular activities are temperature dependent. For example, cooling mammalian cells from their normal body temperature of 37°C to 4°C can virtually “freeze” or stop many cellular processes (e.g., intracellular membrane movements).

Radiant energy is the kinetic energy of photons, or waves of light, and is critical to biology. Radiant energy can be converted to thermal energy, for instance when light is absorbed by molecules and the energy is converted to molecular motion. Radiant energy absorbed by molecules can also change the electronic structure of the molecules, moving electrons into higher-energy orbitals, whence it can later be recovered to perform work. For example, during photosynthesis, light energy absorbed by pigment molecules such as chlorophyll is subsequently converted into the energy of chemical bonds (see Chapter 12).

Mechanical energy, a major form of kinetic energy in biology, usually results from the conversion of stored chemical energy. For example, changes in the lengths of cytoskeletal filaments generate forces that push or pull on membranes and organelles (see Chapters 17 and 18).

Electric energy—the energy of moving electrons or other charged particles—is yet another major form of kinetic energy, one with particular importance to membrane function, such as in electrically active neurons (see Chapter 22).

Several forms of potential energy are biologically significant. Central to biology is **chemical potential energy**, the energy stored in the bonds connecting atoms in molecules. Indeed, most of the biochemical reactions described in this book involve the making or breaking of at least one covalent chemical bond. We recognize this energy when chemicals undergo energy-releasing reactions. For example, the high potential energy in the covalent bonds of glucose can be released by controlled enzymatic combustion in cells (see Chapter 12). This energy is harnessed by the cell to do many kinds of work.

A second biologically important form of potential energy is the energy in a **concentration gradient**. When the concentration of a substance on one side of a barrier, such as a membrane, is different from that on the other side, a concentration gradient exists. All cells form concentration gradients between their interior and the external fluids by selectively exchanging nutrients, waste products, and ions with their surroundings. Also, organelles within cells (e.g., mitochondria, lysosomes) frequently contain different concentrations of ions and other molecules; the concentration of protons within a lysosome, as we saw in the last section, is about 500 times that of the cytoplasm.

A third form of potential energy in cells is an **electric potential**—the energy of charge separation. For instance, there is a gradient of electric charge of ~200,000 volts per cm across the plasma membrane of virtually all cells. We discuss how concentration gradients and the potential difference across cell membranes are generated and maintained in Chapter 11 and how they are converted to chemical potential energy in Chapter 12.

Cells Can Transform One Type of Energy into Another

According to the first law of thermodynamics, energy is neither created nor destroyed but can be converted from one form to another. (In nuclear reactions, mass is converted to energy, but this is irrelevant to biological systems.) Energy

conversions are very important in biology. In photosynthesis, for example, the radiant energy of light is transformed into the chemical potential energy of the covalent bonds between the atoms in a sucrose or starch molecule. In muscles and nerves, chemical potential energy stored in covalent bonds is transformed, respectively, into the kinetic energy of muscle contraction and the electric energy of nerve transmission. In all cells, potential energy—released by breaking certain chemical bonds—is used to generate potential energy in the form of concentration and electric potential gradients. Similarly, energy stored in chemical concentration gradients or electric potential gradients is used to synthesize chemical bonds or to transport molecules from one side of a membrane to another to generate a concentration gradient. The latter process occurs during the transport of nutrients such as glucose into certain cells and transport of many waste products out of cells.

Because all forms of energy are interconvertible, they can be expressed in the same units of measurement. Although the standard unit of energy is the joule, biochemists have traditionally used an alternative unit, the **calorie** (1 joule = 0.239 calorie). A calorie is the amount of energy required to raise the temperature of one gram of water by 1 °C. Throughout this book, we use the kilocalorie to measure energy changes (1 kcal = 1000 cal). When you read or hear about the “Calories” in food (note the capital C), the reference is almost always to kilocalories as defined here.

The Change in Free Energy Determines If a Chemical Reaction Will Occur Spontaneously

Chemical reactions can be divided into two types depending on whether energy is absorbed or released in the process. In an **exergonic** (“energy-releasing”) reaction, the products contain less energy than the reactants. Exergonic reactions take place spontaneously. The liberated energy is usually released as heat (the energy of molecular motion), and generally results in a rise in temperature, such as in the oxidation (burning) of wood. In an **endergonic** (“energy-absorbing”) reaction, the products contain more energy than the reactants and energy is absorbed during the reaction. If there is no external source of energy to drive an endergonic reaction, it cannot take place. Endergonic reactions are responsible for the ability of instant cold packs often used to treat injuries to rapidly cool below room temperature. Crushing the pack mixes the reagents, initiating the reaction.

A fundamentally important concept in understanding if a reaction is exergonic or endergonic, and therefore if it occurs spontaneously or not, is **free energy**, G , named after J. W. Gibbs. Gibbs, who received the first PhD in engineering in America in 1863, showed that “all systems change in such a way that free energy [G] is minimized.” In other words, a chemical reaction occurs spontaneously when the free energy of the products is lower than the free energy of the reactants. In the case of a chemical reaction, reactants $\rightleftharpoons$ products, the free-energy change, ΔG , is given by

$$\Delta G = G_{\text{products}} - G_{\text{reactants}}$$

FIGURE 2-29 Changes in the free energy (ΔG) of exergonic and endergonic reactions. (a) In exergonic reactions, the free energy of the products is lower than that of the reactants. Consequently, these reactions occur spontaneously and energy is released as the reactions proceed. (b) In endergonic reactions, the free energy of the products is greater than that of the reactants and these reactions do not occur spontaneously. An external source of energy must be supplied if the reactants are to be converted into products.

The relation of ΔG to the direction of any chemical reaction can be summarized in three statements:

- If ΔG is negative, the forward reaction will tend to occur spontaneously and energy usually will be released as the reaction takes place (exergonic reaction) (Figure 2-29). A reaction with a negative ΔG is called thermodynamically favorable.
- If ΔG is positive, the forward reaction will not occur spontaneously; energy will have to be added to the system in order to force the reactants to become products (endergonic reaction).
- If ΔG is zero, both forward and reverse reactions occur at equal rates and there will be no spontaneous net conversion of reactants to products, or vice versa; the system is at equilibrium.

By convention, the *standard free-energy change* of a reaction $\Delta G^{\circ'}$ is the value of the change in free energy under the conditions of 298 K (25 °C), 1 atm pressure, pH 7.0 (as in pure water), and initial concentrations of 1 M for all reactants and products except protons, which are kept at 10^{-7} M (pH 7.0). Most biological reactions differ from standard conditions, particularly in the concentrations of reactants, which are normally less than 1 M.

The free energy of a chemical system can be defined as $G = H - TS$, where H is the bond energy, or **enthalpy**, of the system; T is its temperature in degrees Kelvin (K); and S is the **entropy**, a measure of its randomness or disorder. According to the second law of thermodynamics, the natural tendency of any system is to become more disordered—that is, for entropy to increase. A reaction can occur spontaneously only if the combined effects of changes in enthalpy and

entropy lead to a lower ΔG . That is, if temperature remains constant, a reaction proceeds spontaneously only if the free-energy change, ΔG , in the following equation is negative:

$$\Delta G = \Delta H - T\Delta S \quad (2-6)$$

In an **exothermic** (“heat-releasing”) chemical reaction, ΔH is negative. In an **endothermic** (“heat-absorbing”) reaction, ΔH is positive. The combined effects of the changes in the enthalpy and entropy determine if the ΔG for a reaction is positive or negative and thus if the reaction occurs spontaneously. An exothermic reaction ($\Delta H < 0$), in which entropy increases ($\Delta S > 0$), occurs spontaneously ($\Delta G < 0$). An endothermic reaction ($\Delta H > 0$) will occur spontaneously if ΔS increases enough so that the $T\Delta S$ term can overcome the positive ΔH .

Many biological reactions lead to an increase in order and thus a decrease in entropy ($\Delta S < 0$). An obvious example is the reaction that links amino acids to form a protein. A solution of protein molecules has a lower entropy than does a solution of the same amino acids unlinked because the free movement of any amino acid in a protein is more restricted (greater order) when it is bound into a long chain than when it is not. Thus when cells synthesize polymers such as proteins from their constituent monomers, the polymerizing reaction will only be spontaneous if the cells can efficiently transfer energy to both generate the bonds that hold the monomers together and overcome the loss in entropy that accompanies polymerization. Often cells accomplish this feat by “coupling” such synthetic, entropy-lowering reactions with independent reactions that have a very highly negative ΔG (see below). In this way, cells can convert sources of energy in their environment into the building of highly organized structures and metabolic pathways that are essential for life.

The actual change in free energy ΔG during a reaction is influenced by temperature, pressure, and the initial concentrations of reactants and products and usually differs from the standard free-energy change $\Delta G^{\circ'}$. Most biological reactions—like others that take place in aqueous solutions—also are affected by the pH of the solution. We can estimate free-energy changes for temperatures and initial concentrations that differ from the standard conditions by using the equation

$$\Delta G = \Delta G^{\circ'} + RT \ln Q = \Delta G^{\circ'} + RT \ln \frac{[\text{products}]}{[\text{reactants}]} \quad (2-7)$$

where R is the gas constant of 1.987 cal/(degree·mol), T is the temperature (in degrees Kelvin), and Q is the *initial* ratio of products to reactants. For a reaction $A + B \rightleftharpoons C$, in which two molecules combine to form a third, Q in Equation 2-7 equals $[C]/[A][B]$. In this case, an increase in the initial concentration of either $[A]$ or $[B]$ will result in a larger negative value for ΔG and thus drive the reaction toward spontaneous formation of C .

Regardless of the $\Delta G^{\circ'}$ for a particular biochemical reaction, it will proceed spontaneously within cells only if ΔG is

negative, given the intracellular concentrations of reactants and products. For example, the conversion of glyceraldehyde 3-phosphate (G3P) to dihydroxyacetone phosphate (DHAP), two intermediates in the breakdown of glucose,

has a ΔG° of -1840 cal/mol. If the initial concentrations of G3P and DHAP are equal, then $\Delta G = \Delta G^\circ$ because $RT \ln 1 = 0$; in this situation, the reversible reaction $\text{G3P} \rightleftharpoons \text{DHAP}$ will proceed spontaneously in the direction of DHAP formation until equilibrium is reached. However, if the initial [DHAP] is 0.1 M and the initial [G3P] is 0.001 M, with other conditions standard, then Q in Equation 2-7 equals $0.1/0.001 = 100$, giving a ΔG of $+887$ cal/mol. Under these conditions, the reaction will proceed in the direction of formation of G3P.

The ΔG for a reaction is independent of the reaction rate. Indeed, under usual physiological conditions, few if any of the biochemical reactions needed to sustain life would occur without some mechanism for increasing reaction rates. As we describe below and in more detail in Chapter 3, the rates of reactions in biological systems are usually determined by the activity of **enzymes**, the protein catalysts that accelerate the formation of products from reactants without altering the value of ΔG .

The ΔG° of a Reaction Can Be Calculated from Its K_{eq}

A chemical mixture at equilibrium is in a stable state of minimal free energy. For a system at equilibrium ($\Delta G = 0$, $Q = K_{\text{eq}}$), we can write

$$\Delta G^\circ = -2.3RT \log K_{\text{eq}} = -1362 \log K_{\text{eq}} \quad (2-8)$$

under standard conditions (note the change to base 10 logarithms). Thus if we determine the concentrations of reactants and products at equilibrium (i.e., the K_{eq}), we can calculate the value of ΔG° . For example, the K_{eq} for the interconversion of glyceraldehyde 3-phosphate to dihydroxyacetone phosphate ($\text{G3P} \rightleftharpoons \text{DHAP}$) is 22.2 under standard conditions. Substituting this value into Equation 2-8, we can easily calculate the ΔG° for this reaction as -1840 cal/mol.

By rearranging Equation 2-8 and taking the antilogarithm, we obtain

$$K_{\text{eq}} = 10^{-(\Delta G^\circ/2.3RT)} \quad (2-9)$$

From this expression, it is clear that if ΔG° is negative, the exponent will be positive and hence K_{eq} will be greater than 1. Therefore, at equilibrium there will be more products than reactants; in other words, the formation of products from reactants is favored. Conversely, if ΔG° is positive, the exponent will be negative and K_{eq} will be less than 1. The relationship between K_{eq} and ΔG° further emphasizes the influence of relative free energies of reactants and

products on the extent to which a reaction will occur spontaneously.

The Rate of a Reaction Depends on the Activation Energy Necessary to Energize the Reactants into a Transition State

As a chemical reaction proceeds, reactants approach each other; some bonds begin to form while others begin to break. One way to think of the state of the molecules during this transition is that there are strains in the electronic configurations of the atoms and their bonds. The collection of atoms moves from the relatively stable state of the reactants to this transient, intermediate, and higher-energy state during the course of the reaction (Figure 2-30). The state during a chemical reaction at which the system is at its highest energy level is called the **transition state**, and the collection of reactants in that state is called the **transition-state intermediate**. The energy needed to excite the reactants to this higher-energy state is called the **activation energy** of the reaction. The activation energy is usually represented by $\Delta G^\ddagger$, analogous to the representation of the change in Gibbs free energy (ΔG) already discussed. From the transition state, the collection of atoms can either release energy as the reaction products are formed or release energy as the atoms go “backward” and re-form the original reactants. The velocity (V) at which products are generated from reactants during the reaction under a given set of conditions (temperature, pressure, reactant concentrations) will depend on the concentration of

FIGURE 2-30 Activation energy of uncatalyzed and catalyzed chemical reactions. This hypothetical reaction pathway (blue) depicts the changes in free energy, G , as a reaction proceeds. A reaction will take place spontaneously if the free energy (G) of the products is less than that of the reactants ($\Delta G < 0$). However, all chemical reactions proceed through one (shown here) or more high-energy transition states, and the rate of a reaction is inversely proportional to the activation energy ($\Delta G^\ddagger$), which is the difference in free energy between the reactants and the transition state. In a catalyzed reaction (red), the free energies of the reactants and products are unchanged but the free energy of the transition state is lowered, thus increasing the velocity of the reaction.

material in the transition state, which in turn will depend on the activation energy and the characteristic rate constant (ν) at which the transition state is converted to products. The higher the activation energy, the lower the fraction of reactants that reach the transition state and the slower the overall rate of the reaction. The relationship between the concentration of reactants, ν , and V is

$$V = \nu [\text{reactants}] \times 10^{-(\Delta G^\ddagger/2.3RT)}$$

From this equation, we can see that lowering the activation energy—that is, decreasing the free energy of the transition state $\Delta G^\ddagger$ —leads to an acceleration of the overall reaction rate V . A reduction in $\Delta G^\ddagger$ of 1.36 kcal/mol leads to a ten-fold increase in the rate of the reaction, whereas a 2.72 kcal/mol reduction increases the rate 100-fold. Thus relatively small changes in $\Delta G^\ddagger$ can lead to large changes in the overall rate of the reaction.

Catalysts such as enzymes (discussed further in Chapter 3) accelerate reaction rates by lowering the relative energy of the transition state and so the activation energy required to reach it (see Figure 2-30). The relative energies of reactants and products will determine if a reaction is thermodynamically favorable (negative ΔG), whereas the activation energy will determine how rapidly products form—that is, its reaction kinetics. Thermodynamically favorable reactions will not occur at appreciable rates if the activation energies are too high.

Life Depends on the Coupling of Unfavorable Chemical Reactions with Energetically Favorable Ones

Many processes in cells are energetically unfavorable ($\Delta G > 0$) and will not proceed spontaneously. Examples include the synthesis of DNA from nucleotides and transport of a substance across the plasma membrane from a lower to a higher concentration. Cells can carry out an energy-requiring, or endergonic, reaction ($\Delta G_1 > 0$) by coupling it to an energy-releasing, or exergonic, reaction ($\Delta G_2 < 0$) if the sum of the two reactions has an overall net negative ΔG .

Suppose, for example, that the reaction $A \rightleftharpoons B + X$ has a ΔG of +5 kcal/mol and that the reaction $X \rightleftharpoons Y + Z$ has a ΔG of -10 kcal/mol:

In the absence of the second reaction, there would be much more A than B at equilibrium. However, because the conversion of X to Y + Z is such a favorable reaction, it will pull the first process toward the formation of B and the consumption of A. Energetically unfavorable reactions in cells often are coupled to the energy-releasing hydrolysis of ATP, as we discuss next.

Hydrolysis of ATP Releases Substantial Free Energy and Drives Many Cellular Processes

In almost all organisms, the nucleoside triphosphate adenosine triphosphate, or ATP (Figure 2-31), is the most important molecule for capturing, transiently storing, and subsequently transferring energy to perform work (e.g., biosynthesis, mechanical motion). Commonly referred to as a cell's energy "currency," ATP is a type of usable energy that cells can "spend" in order to power their activities. The storied history of ATP begins with its discovery in 1929 apparently simultaneously by Kurt Lohmann, who was working with the great biochemist Otto Meyerhof in Germany and who published first, and by Cyrus Fiske and Yellagapada SubbaRow in the United States. Muscle contractions were shown to depend on ATP in the 1930s. The proposal that ATP is the main intermediary for the transfer of energy in cells is credited to Fritz Lipmann around 1941. Many Nobel Prizes have been awarded for the study of ATP and its role in cellular energy metabolism, and its importance in understanding molecular cell biology cannot be overstated.

The useful energy in an ATP molecule is contained in phosphoanhydride bonds, which are covalent bonds formed

FIGURE 2-31 Hydrolysis of adenosine triphosphate (ATP).

The two phosphoanhydride bonds (red) in ATP (top), which link the three phosphate groups, each have a ΔG° of about -7.3 kcal/mol for hydrolysis. Hydrolysis of the terminal phosphoanhydride bond by the addition of water results in the release of phosphate and generation of ADP. Hydrolysis of the phosphoanhydride bonds of ATP, especially the terminal one, is the source of energy that drives many energy-requiring reactions in biological systems.

from the condensation of two molecules of phosphate by the loss of water:

As shown in Figure 2-31, an ATP molecule has two key phosphoanhydride (also called phosphodiester) bonds. Forming these bonds in ATP requires an input of energy. When these bonds are hydrolyzed, or broken by the addition of water, that energy is released. Hydrolysis of a phosphoanhydride bond (represented by the symbol $\sim$) in each of the following reactions has a highly negative ΔG° of about -7.3 kcal/mol:

In these reactions that occur in biological systems, P_i stands for inorganic phosphate (PO_4^{3-}) and PP_i for inorganic pyrophosphate, two phosphate groups linked by a phosphoanhydride bond. As the top two reactions show, the removal of a phosphate or a pyrophosphate group from ATP leaves adenosine diphosphate (ADP) or adenosine monophosphate (AMP), respectively.

A phosphoanhydride bond or other “high-energy bond” (commonly denoted by $\sim$) is not intrinsically different from other covalent bonds. High-energy bonds simply release substantial amounts of energy when hydrolyzed. For instance, the ΔG° for hydrolysis of a phosphoanhydride bond in ATP (-7.3 kcal/mol) is more than three times the ΔG° for hydrolysis of the phosphoester bond (red) in glycerol 3-phosphate (-2.2 kcal/mol):

A principal reason for this difference is that ATP and its hydrolysis products ADP and P_i are highly charged at neutral pH. During synthesis of ATP, a large input of energy is required to force the negative charges in ADP and P_i together. Conversely, this energy is released when ATP is hydrolyzed to ADP and P_i . In comparison, formation of the phosphoester bond between an uncharged hydroxyl in glycerol and P_i

requires less energy, and less energy is released when this bond is hydrolyzed.

Cells have evolved protein-mediated mechanisms for transferring the free energy released by hydrolysis of phosphoanhydride bonds to other molecules, thereby driving reactions that would otherwise be energetically unfavorable. For example, if the ΔG for the reaction $\text{B} + \text{C} \rightarrow \text{D}$ is positive but less than the ΔG for hydrolysis of ATP, the reaction can be driven to the right by coupling it to hydrolysis of the terminal phosphoanhydride bond in ATP. In one common mechanism of such *energy coupling*, some of the energy stored in this phosphoanhydride bond is transferred to one of the reactants by breaking the bond in ATP and forming a covalent bond between the released phosphate group and one of the reactants. The phosphorylated intermediate generated in this way can then react with C to form $\text{D} + \text{P}_i$ in a reaction that has a negative ΔG :

The overall reaction

is energetically favorable ($\Delta G < 0$).

An alternative mechanism of energy coupling is to use the energy released by ATP hydrolysis to change the conformation of the molecule to an “energy-rich” stressed state. In turn, the energy stored as conformational stress can be released as the molecule “relaxes” back into its unstressed conformation. If this relaxation process can be mechanistically coupled to another reaction, the released energy can be harnessed to drive important cellular processes.

As with many biosynthetic reactions, transport of molecules into or out of the cell often has a positive ΔG and thus requires an input of energy to proceed. Such simple transport reactions do not *directly* involve the making or breaking of covalent bonds; thus the ΔG° is 0. In the case of a substance moving into a cell, Equation 2-7 becomes

$$\Delta G = RT \ln \frac{[\text{C}_{\text{in}}]}{[\text{C}_{\text{out}}]} \quad (2-10)$$

where $[\text{C}_{\text{in}}]$ is the initial concentration of the substance inside the cell and $[\text{C}_{\text{out}}]$ is its concentration outside the cell. We can see from Equation 2-10 that ΔG is positive for transport of a substance into a cell against its concentration gradient (when $[\text{C}_{\text{in}}] > [\text{C}_{\text{out}}]$); the energy to drive such “uphill” transport often is supplied by the hydrolysis of ATP. Conversely, when a substance moves down its concentration gradient ($[\text{C}_{\text{out}}] > [\text{C}_{\text{in}}]$), ΔG is negative. Such “downhill” transport releases energy that can be coupled to an energy-requiring reaction, say, the movement of another substance uphill across a membrane or the synthesis of ATP itself (see Chapters 11 and 12).

ATP Is Generated During Photosynthesis and Respiration

ATP is continually being hydrolyzed to provide energy for many cellular activities. Some estimates suggest that humans daily hydrolyze a mass of ATP equal to their entire body weight. Clearly, to continue functioning, cells must constantly replenish their ATP supply. Constantly replenishing ATP requires that cells continually obtain energy from their environment. For nearly all cells, the ultimate source of energy used to make ATP is sunlight. Some organisms can use sunlight directly. Through the process of **photosynthesis**, plants, algae, and certain photosynthetic bacteria trap the energy of sunlight and use it to synthesize ATP from ADP and P_i . Much of the ATP produced in photosynthesis is hydrolyzed to provide energy for the conversion of carbon dioxide to six-carbon sugars, a process called **carbon fixation**:

The sugars made during photosynthesis are a source of food, and thus energy, for the plants or other photosynthetic organisms making them and for the non-photosynthetic organisms, such as animals, that either consume the plants directly or indirectly by eating other animals that have eaten the plants. In this way sunlight is the direct or indirect source of energy for most organisms (see Chapter 12).

In plants, animals, and nearly all other organisms, the free energy in sugars and other molecules derived from food is released in the processes of **glycolysis** and **cellular respiration**. During cellular respiration, energy-rich molecules in food (e.g., glucose) are oxidized to carbon dioxide and water. The complete oxidation of glucose,

has a ΔG° of -686 kcal/mol and is the reverse of photosynthetic carbon fixation. Cells employ an elaborate set of protein-mediated reactions to couple the oxidation of 1 molecule of glucose to the synthesis of as many as 30 molecules of ATP from 30 molecules of ADP. This oxygen-dependent (**aerobic**) degradation (**catabolism**) of glucose is the major pathway for generating ATP in all animal cells, non-photosynthetic plant cells, and many bacterial cells. Catabolism of fatty acids can also be an important source of ATP. We discuss the mechanisms of photosynthesis and cellular respiration in Chapter 12.

Although light energy captured in photosynthesis is the primary source of chemical energy for cells, it is not the only source. Certain microorganisms that live in or around deep ocean vents, where adequate sunlight is unavailable, derive the energy for converting ADP and P_i into ATP from the oxidation of reduced inorganic compounds. These reduced compounds originate deep in the earth and are released at the vents.

NAD^+ and FAD Couple Many Biological Oxidation and Reduction Reactions

In many chemical reactions, electrons are transferred from one atom or molecule to another; this transfer may or may not accompany the formation of new chemical bonds or the release of energy that can be coupled to other reactions. The loss of electrons from an atom or a molecule is called **oxidation**, and the gain of electrons by an atom or a molecule is called **reduction**. An example of oxidation is the removal of electrons from the sulfhydryl groups of two cysteines to form a disulfide bond, described above in Section 2.2. Because electrons are neither created nor destroyed in a chemical reaction, if one atom or molecule is oxidized, another must be reduced. For example, oxygen draws electrons from Fe^{2+} (ferrous) ions to form Fe^{3+} (ferric) ions, a reaction that occurs as part of the process by which carbohydrates are degraded in mitochondria. Each oxygen atom receives two electrons, one from each of two Fe^{2+} ions:

Thus Fe^{2+} is oxidized and O_2 is reduced. Such reactions in which one molecule is reduced and another oxidized often are referred to as **redox reactions**. Oxygen is an electron acceptor in many redox reactions in cells under aerobic conditions.

Many biologically important oxidation and reduction reactions involve the removal or the addition of hydrogen atoms (protons plus electrons) rather than the transfer of isolated electrons on their own. The oxidation of succinate to fumarate, which also occurs in mitochondria, is an example (Figure 2-32). Protons are soluble in aqueous solutions (as H_3O^+), but electrons are not and must be transferred directly from one atom or molecule to another without a water-dissolved intermediate. In this type of oxidation reaction, electrons often are transferred to small electron-carrying molecules, sometimes referred to as coenzymes. The most common of these electron carriers are NAD^+ (nicotinamide adenine dinucleotide), which is reduced to NADH, and FAD (flavin adenine dinucleotide), which is reduced to FADH_2 (Figure 2-33). The reduced forms of these coenzymes can transfer protons and electrons to other molecules, thereby reducing them.

FIGURE 2-32 Conversion of succinate to fumarate. In this oxidation reaction, which occurs in mitochondria as part of the citric acid cycle, succinate loses two electrons and two protons. These are transferred to FAD, reducing it to FADH_2 .

FIGURE 2-33 The electron-carrying coenzymes NAD⁺ and FAD.

(a) NAD⁺ (nicotinamide adenine dinucleotide) is reduced to NADH by the addition of two electrons and one proton simultaneously. In many biological redox reactions, a pair of hydrogen atoms (two protons and two electrons) are removed from a molecule. In some cases, one of the protons and both electrons are transferred to NAD⁺; the other proton

is released into solution. (b) FAD (flavin adenine dinucleotide) is reduced to FADH₂ by the addition of two electrons and two protons, as occurs when succinate is converted to fumarate (see Figure 2-32). In this two-step reaction, addition of one electron together with one proton first generates a short-lived semiquinone intermediate (not shown), which then accepts a second electron and proton.

To describe redox reactions, such as the reaction of ferrous ion (Fe²⁺) and oxygen (O₂), it is easiest to divide them into two half-reactions:

In this case, the reduced oxygen (O²⁻) readily reacts with two protons to form one water molecule (H₂O). The readiness with which an atom or a molecule *gains* an electron is its **reduction potential** *E*. The tendency to *lose* electrons, the **oxidation potential**, has the same magnitude but opposite sign as the reduction potential for the reverse reaction.

Reduction potentials are measured in volts (V) from an arbitrary zero point set at the reduction potential of the following half-reaction under standard conditions (25 °C, 1 atm, and reactants at 1 M):

The value of *E* for a molecule or an atom under standard conditions is its standard reduction potential, *E*'₀. A molecule or an ion with a positive *E*'₀ has a higher affinity for electrons than the H⁺ ion does under standard conditions. Conversely, a molecule or ion with a negative *E*'₀ has a lower affinity for electrons than the H⁺ ion does under standard conditions. Like the values of Δ*G*'₀, standard reduction potentials may differ somewhat from those found under the conditions in a cell because the concentrations of reactants in a cell are not 1 M.

In a redox reaction, electrons move spontaneously toward atoms or molecules having *more positive* reduction potentials. In other words, a molecule having a more negative reduction potential can transfer electrons spontaneously

to, or reduce, a molecule with a more positive reduction potential. In this type of reaction, the change in electric potential Δ*E* is the sum of the reduction and oxidation potentials for the two half-reactions. The Δ*E* for a redox reaction is related to the change in free energy Δ*G* by the following expression:

$$\Delta G \text{ (cal/mol)} = -n (23,064) \Delta E \text{ (volts)} \quad (2-11)$$

where *n* is the number of electrons transferred. Note that a redox reaction with a positive Δ*E* value will have a negative Δ*G* and thus will tend to proceed spontaneously from left to right.

KEY CONCEPTS of Section 2.4

Biochemical Energetics

- The change in free energy, Δ*G*, is the most useful measure for predicting the potential of chemical reactions to occur spontaneously in biological systems. Chemical reactions tend to proceed spontaneously in the direction for which Δ*G* is negative. The magnitude of Δ*G* is independent of the reaction rate. A reaction with a negative Δ*G* is called thermodynamically favorable.
- The chemical free-energy change, Δ*G*'₀, equals $-2.3 RT \log K_{\text{eq}}$. Thus the value of Δ*G*'₀ can be calculated from the experimentally determined concentrations of reactants and products at equilibrium.
- The rate of a reaction depends on the activation energy needed to energize reactants to a transition state. Catalysts such as enzymes speed up reactions by lowering the activation energy of the transition state.

- A chemical reaction having a positive ΔG can proceed if it is coupled with a reaction having a negative ΔG of larger magnitude.
- Many otherwise energetically unfavorable cellular processes are driven by the hydrolysis of phosphoanhydride bonds in ATP (see Figure 2-31).
- Directly or indirectly, light energy captured by photosynthesis in plants, algae, and photosynthetic bacteria is the ultimate source of chemical energy for nearly all cells on earth.
- An oxidation reaction (loss of electrons) is always coupled with a reduction reaction (gain of electrons).
- Biological oxidation and reduction reactions often are coupled by electron-carrying coenzymes such as NAD^+ and FAD (see Figure 2-33).
- Oxidation-reduction reactions with a positive ΔE have a negative ΔG and thus tend to proceed spontaneously.

Key Terms

Review the Concepts

1. The gecko is a reptile with an amazing ability to climb smooth surfaces, including glass. Recent discoveries indicate that geckos stick to smooth surfaces via van der Waals interactions between septae on their feet and the smooth surface. How is this method of stickiness advantageous over covalent interactions? Given that van der Waals forces are among the weakest molecular interactions, how can the gecko's feet stick so effectively?
2. The K^+ channel is an example of a transmembrane protein (a protein that spans the phospholipid bilayer of the plasma membrane). What types of amino acids are likely to be found (a) lining the channel through which K^+ passes, (b) in contact with the hydrophobic core of the phospholipid bilayer containing fatty acyl groups, (c) in the cytosolic domain of the protein, and (d) in the extracellular domain of the protein?
3. V-M-Y-F-E-N: This is the single-letter amino acid abbreviation for a peptide. What is the net charge of this peptide at pH 7.0? An enzyme called a protein tyrosine kinase can attach phosphates to the hydroxyl groups of tyrosine. What is the net charge of the peptide at pH 7.0 after it has been phosphorylated by a tyrosine kinase? What is the likely source of phosphate utilized by the kinase for this reaction?
4. Disulfide bonds help to stabilize the three-dimensional structure of proteins. What amino acids are involved in the formation of disulfide bonds? Does the formation of a disulfide bond increase or decrease entropy (ΔS)?
5. In the 1960s, the drug thalidomide was prescribed to pregnant women to treat morning sickness. However, thalidomide caused severe limb defects in the children of some women who took the drug, and its use for morning sickness was discontinued. It is now known that thalidomide was administered as a mixture of two stereoisomeric compounds, one of which relieved morning sickness and the other of which was responsible for the birth defects. What are stereoisomers? Why might two such closely related compounds have such different physiologic effects?
6. Name the compound shown below.

Is this nucleotide a component of DNA, RNA, or both? Name one other function of this compound.

7. The chemical basis of blood-group specificity resides in the carbohydrates displayed on the surface of red blood cells. Carbohydrates have the potential for great structural diversity. Indeed, the structural complexity of the oligosaccharides that can be formed from four sugars is greater than that for oligopeptides from four amino acids. What properties of carbohydrates make this great structural diversity possible?

8. Calculate the pH of 1 L of pure water at equilibrium. How will the pH change after 0.008 moles of the strong base NaOH are dissolved in the water? Now, calculate the pH of a 50 mM aqueous solution of the weak acid 3-(*N*-morpholino) propane-1-sulfonic acid (MOPS) in which 61% of the solute is in its weak acid form and 39% is in the form of MOPS conjugate base (the pK_a for MOPS is 7.20). What is the final pH after 0.008 moles of NaOH are added to 1 L of this MOPS buffer?

9. Ammonia (NH_3) is a weak base that under acidic conditions becomes protonated to the ammonium ion in the following reaction:

NH_3 freely permeates biological membranes, including those of lysosomes. The lysosome is a subcellular organelle with a pH of about 4.5–5.0; the pH of cytoplasm is ~ 7.0 . What is the effect on the pH of the fluid content of lysosomes when cells are exposed to ammonia? *Note:* Protonated ammonia does not diffuse freely across membranes.

10. Consider the binding reaction $\text{L} + \text{R} \rightarrow \text{LR}$, where L is a ligand and R is its receptor. When $1 \times 10^{-3} \text{ M}$ L is added to a solution containing $5 \times 10^{-2} \text{ M}$ R, 90 percent of the L binds to form LR. What is the K_{eq} of this reaction? How will the K_{eq} be affected by the addition of a protein that facilitates (catalyzes) this binding reaction? What is the dissociation equilibrium constant K_d ?

11. What is the ionization state of phosphoric acid in the cytoplasm? Why is phosphoric acid such a physiologically important compound?

12. The ΔG° for the reaction $\text{X} + \text{Y} \rightarrow \text{XY}$ is -1000 cal/mol . What is the ΔG at 25°C (298 Kelvin) starting with 0.01 M each X, Y, and XY? Suggest two ways one could make this reaction energetically favorable.

13. According to health experts, saturated fatty acids, which come from animal fats, are a major factor contributing to coronary heart disease. What distinguishes a saturated fatty acid from an unsaturated fatty acid, and to what does the term *saturated* refer? Recently, trans unsaturated fatty acids, or trans fats, which raise total cholesterol levels in the body, have also been implicated in heart disease. How does the cis stereoisomer differ from the trans configuration, and what effect does the cis configuration have on the structure of the fatty acid chain?

14. Chemical modifications to amino acids contribute to the diversity and function of proteins. For instance, γ -carboxylation of specific amino acids is required to make some proteins

biologically active. What particular amino acid undergoes this modification, and what is the biological relevance? Warfarin, a derivative of coumarin, which is present in many plants, inhibits γ -carboxylation of this amino acid and was used in the past as a rat poison. At present, it is also used clinically in humans. What patients might be prescribed warfarin and why?

Analyze the Data

1. During much of the “Age of Enlightenment” in eighteenth-century Europe, scientists toiled under the belief that living things and the inanimate world were fundamentally distinct forms of matter. Then in 1828, Friedrich Wöhler showed that he could synthesize urea, a well-known waste product of animals, from the minerals silver isocyanate and ammonium chloride. “I can make urea without kidneys!” he is said to have remarked. Of Wöhler’s discovery the preeminent chemist Justus von Liebig wrote in 1837 that the “production of urea without the assistance of vital functions . . . must be considered one of the discoveries with which a new era in science has commenced.” Slightly more than 100 years later, Stanley Miller discharged sparks into a mixture of H_2O , CH_4 , NH_3 , and H_2 in an effort to simulate the chemical conditions of an ancient reducing earth atmosphere (the sparks mimicked lightning striking a primordial sea or “soup”) and identified many biomolecules in the resulting mixture, including amino acids and carbohydrates. What do these experiments suggest about the nature of biomolecules and the relationship between organic (living) and inorganic (nonliving) matter? What do they suggest about the evolution of life? What do they indicate about the value of chemistry in understanding living things?

2. The graph below illustrates the effect that the addition of a strong base such as sodium hydroxide has on the pH of an aqueous 0.1 M solution of an amino acid. Assume that prior to the addition of any OH^- , the entire dissolved amino acid

sample is in its fully protonated form. The addition of OH^- causes the expected steep increase in solution pH until, between roughly 0.03–0.07 M NaOH, the solution pH remains almost constant at a pH of approximately 1.8. What causes the resistance to change pH in this range? What are solutions that resist changes in pH called? What organic chemical group on the amino acid is most likely responsible for this phenomenon at pH 1.8? Additional base causes the pH to again increase rapidly until the base concentration reaches 0.15 M and 0.25 M, at which points the solution pH hovers around values of 6 and 9.3, respectively. What is the significance of these pH values? Which amino acid do you suspect is being titrated?

Molecular model of the proteasome from the heat- and acid-loving archaeon *T. acidophilum*, represented using both solvent-accessible surfaces (*bottom*) and ribbons (*top*). Proteasomes are protein-digesting molecular machines, comprising a middle catalytic core (red, beige, and gray), where degradation takes place, and two regulatory subunit caps (yellow and black), which recognize proteins that have been tagged for destruction by the addition of ubiquitin molecules. [Ramon Andrade 3Dciencia/Science Photo Library.]

Proteins, which are polymers of amino acids, come in many sizes and shapes. Their three-dimensional diversity principally reflects variations in their lengths and amino acid sequences. In general, the linear, unbranched polymer of amino acids composing any protein will fold into only one or a few closely related three-dimensional shapes—called **conformations**. The conformation of a protein together with the distinctive chemical properties of its amino acid side chains determines its function. Because of their many different shapes and chemical properties, proteins can perform a dazzling array of distinct functions inside and outside cells that either are essential for life or provide selective evolutionary advantage to the cell or organism that contains them. It is, therefore, not surprising that characterizing the structures and activities of proteins is a fundamental prerequisite for

Protein Structure and Function

understanding how cells work. Much of this textbook is devoted to examining how proteins act together to allow cells to live and function properly.

Although their structures are diverse, most individual proteins can be grouped into one of a few broad functional classes. *Structural proteins*, for example, determine the shapes of cells and their extracellular environments and serve as guide wires or rails to direct the intracellular movement of molecules and organelles. They usually are formed by the assembly of multiple protein subunits into very large, long structures. *Scaffold proteins* bring other proteins together into ordered arrays to perform specific functions more efficiently than if those proteins were not assembled together. *Enzymes* are proteins that catalyze chemical reactions. *Membrane transport proteins* permit the flow of ions

and molecules across cellular membranes. *Regulatory proteins* act as signals, sensors, and switches to control the activities of cells by altering the functions of other proteins and genes. Regulatory proteins include *signaling proteins*, such as hormones and cell-surface receptors that transmit extracellular signals to the cell interior. *Motor proteins* are responsible for moving other proteins, organelles, cells—even whole organisms. Any one protein can be a member of more than one protein class, as is the case with some cell-surface signaling receptors that are both enzymes and regulator proteins because they transmit signals from outside to inside cells by catalyzing chemical reactions. To accomplish efficiently their diverse missions, some proteins assemble into large complexes, often called *molecular machines*.

How do proteins perform so many diverse functions? They do this by exploiting a few simple activities. Most fundamentally, proteins *bind*—to one another, to other macromolecules such as DNA, and to small molecules and ions. In many cases such binding induces a conformational change in the protein and thus influences its activity. Binding is based on molecular complementarity between a protein and its binding partner, as described in Chapter 2. A second key activity is enzymatic *catalysis*. Appropriate folding of a protein will place some amino acid side chains and carboxyl and amino groups of its backbone into positions that permit the catalysis of covalent bond rearrangements. A third activity involves *folding* into a channel or pore within a membrane through which molecules and ions flow. Although these are especially crucial protein activities, they are not the only ones. For example, fish that live in frigid waters—the Antarctic borchs and Arctic cods—have antifreeze proteins in their circulatory systems to prevent water crystallization.

A complete understanding of how proteins permit cells to live and thrive requires the identification and characterization of all the proteins used by a cell. In a sense, molecular cell biologists want to compile a complete protein “parts list” and construct a “user’s manual” that describes how these proteins work. Compiling a comprehensive inventory of proteins has become feasible in recent years with the sequencing of entire *genomes*—complete sets of genes—of more and more organisms. From a computer analysis of genome sequences, researchers can deduce the amino acid sequences and approximate number of the encoded proteins (see Chapter 5). The term *proteome* was coined to refer to the entire protein complement of an organism. The human genome contains some 20,000–23,000 genes that encode proteins. However, variations in mRNA production, such as alternative splicing (see Chapter 8), and more than 100 types of protein modifications may generate hundreds of thousands of distinct human proteins. By comparing the sequences and structures of proteins of unknown function to those of known function, scientists can often deduce much about what these proteins do. In the past, characterization of protein function by genetic, biochemical, or physiological methods often preceded the identification of particular proteins. In the modern genomic and proteomic era, a protein is usually identified prior to determining its function.

FIGURE 3-1 Overview of protein structure and function.

(a) Proteins have a hierarchical structure. A polypeptide’s linear sequence of amino acids linked by peptide bonds (primary structure) folds into local helices or sheets (secondary structure) that pack into a complex three-dimensional shape (tertiary structure). Some individual polypeptides associate into multichain complexes (quaternary structure), which in some cases can be very large, consisting of tens to hundreds of subunits (supramolecular complexes). (b) Proteins perform numerous functions, including organizing in three-dimensional space the genome, organelles, the cytoplasm, protein complexes, and membranes (structure); controlling protein activity (regulation); monitoring the environment and transmitting information (signaling); moving small molecules and ions across membranes (transport); catalyzing chemical reactions (via enzymes); and generating force for movement (via motor proteins). These functions and others arise from specific binding interactions and conformational changes in the structure of a properly folded protein.

In this chapter, we begin our study of how the structure of a protein gives rise to its function, a theme that recurs throughout this book (Figure 3-1). The first section examines how linear chains of amino acid building blocks are arranged in a three-dimensional structural hierarchy. The next section discusses how proteins fold into these structures. We then turn to protein function, focusing on enzymes, the special class of proteins that catalyze chemical reactions. Various mechanisms that cells use to control the activities and life spans of proteins are covered next. The chapter concludes with a discussion of commonly used techniques for identifying, isolating, and characterizing proteins, including a discussion of the burgeoning field of proteomics.

3.1 Hierarchical Structure of Proteins

A protein chain folds into a distinct three-dimensional shape that is stabilized primarily by noncovalent interactions between regions in the linear sequence of amino acids. A key concept in understanding how proteins work is that *function is derived from three-dimensional structure, and three-dimensional structure is determined by both a protein's amino acid sequence and intramolecular noncovalent interactions*. Principles relating biological structure and function initially were formulated by the biologists Johann von Goethe (1749–1832), Ernst Haeckel (1834–1919), and D'Arcy Thompson (1860–1948), whose work has been widely influential in biology and beyond. Indeed, their ideas greatly influenced the school of “organic” architecture pioneered in the early twentieth century that is epitomized by the dicta “form follows function” (Louis Sullivan) and “form is function” (Frank Lloyd Wright). Here we consider the architecture of proteins at four levels of organization: primary, secondary, tertiary, and quaternary (Figure 3-2).

FIGURE 3-2 Four levels of protein hierarchy. (a) The linear sequence of amino acids linked together by peptide bonds is the primary structure. (b) Folding of the polypeptide chain into local α helices or β sheets represents secondary structure. (c) Secondary structural elements together with various loops and turns in a single polypeptide chain pack into a larger independently stable structure, which may include distinct domains; this is tertiary structure. (d) Some proteins consist of more than one polypeptide associated together in a quaternary structure.

The Primary Structure of a Protein Is Its Linear Arrangement of Amino Acids

As discussed in Chapter 2, proteins are polymers constructed out of 20 different types of amino acids. Individual amino acids are linked together in linear, unbranched chains by covalent amide bonds, called **peptide bonds**. Peptide bond formation between the amino group of one amino acid and the carboxyl group of another results in the net release of a water molecule and thus is a form of dehydration reaction (Figure 3-3a). The repeated amide N, α carbon (C_α), carbonyl C, and oxygen atoms of each amino acid residue form

FIGURE 3-3 Structure of a polypeptide. (a) Individual amino acids are linked together by peptide bonds, which form via reactions that result in a loss of water (dehydration). R_1 , R_2 , etc., represent the side chains (“R groups”) of amino acids. (b) Linear polymers of peptide-bond-linked amino acids are called *polypeptides*, which have a free amino end (N-terminus) and a free carboxyl end (C-terminus). (c) A ball-and-stick model shows peptide bonds (yellow) linking the amino nitrogen atom (blue) of one amino acid (aa) with the carbonyl carbon atom (gray) of an adjacent one in the chain. The R groups (green) extend from the α carbon atoms (black) of the amino acids. These side chains largely determine the distinct properties of individual proteins.

the backbone of a protein molecule from which the various side-chain groups project (Figure 3-3b, c). As a consequence of the peptide linkage, the backbone exhibits directionality, usually referred to as an N-to-C orientation, because all the amino groups are located on the same side of the C_α atoms. Thus one end of a protein has a free (unlinked) amino group (the *N-terminus*), and the other end has a free carboxyl group (the *C-terminus*). The sequence of a protein chain is conventionally written with its N-terminal amino acid on the left and its C-terminal amino acid on the right, and the amino acids are numbered sequentially starting from the amino terminus.

The **primary structure** of a protein is simply the linear covalent arrangement, or sequence, of the amino acid residues that compose it. The first primary structure of a protein determined was that of insulin in the early 1950s and today the number of known sequences exceeds 10 million and is growing daily. Many terms are used to denote the chains formed by the polymerization of amino acids. A short chain of amino acids linked by peptide bonds and having a defined sequence is called an **oligopeptide**, or just **peptide**; longer chains are referred to as **polypeptides**. Peptides generally contain fewer than 20–30 amino acid residues, whereas polypeptides are often 200–500 residues long. The longest protein described to date is the muscle protein titin with >35,000 residues. We generally reserve the term **protein** for a polypeptide (or complex of polypeptides) that has a well-defined three-dimensional structure.

The size of a protein or a polypeptide is expressed either as its mass in **daltons** (a dalton is 1 atomic mass unit) or as its molecular weight (MW), which is a dimensionless number equal to the mass in daltons. For example, a 10,000-MW protein has a mass of 10,000 daltons (Da), or 10 kilodaltons (kDa). Later in this chapter, we will consider different methods for measuring the sizes and other physical characteristics of proteins. The proteins encoded by the yeast genome have an average molecular weight of 52,728 and contain, on average, 466 amino acid residues. The average molecular weight of amino acids in proteins is 113, taking into account their average relative abundances. This value can be used to estimate the number of residues in a protein from its molecular weight or, conversely, its molecular weight from the number of residues.

Secondary Structures Are the Core Elements of Protein Architecture

The second level in the hierarchy of protein structure is **secondary structure**. Secondary structures are stable spatial arrangements of segments of a polypeptide chain held together by hydrogen bonds between backbone amide and carbonyl groups and often involving repeating structural patterns. A single polypeptide may contain multiple types of secondary structure in various portions of the chain, depending on its sequence. The principal secondary structures are the **alpha (α) helix**, the **beta (β) sheet**, and a short U-shaped **beta (β) turn**. Parts of the polypeptide that don't form these structures but nevertheless have a well-defined, stable shape are said to have an *irregular* structure. The term *random coil* applies to

highly flexible parts of a polypeptide chain that have no fixed three-dimensional structure. In an average protein, 60 percent of the polypeptide chain exists as α helices and β sheets; the remainder of the molecule is in irregular structures, coils and turns. Thus α helices and β sheets are the major internal supportive elements in most proteins. In this section, we explore the shapes of secondary structures and the forces that favor their formation. In later sections, we examine how arrays of secondary structure fold together into larger, more complex arrangements called tertiary structure.

The α Helix In a polypeptide segment folded into an α helix, the backbone forms a spiral structure in which the carbonyl oxygen atom of each peptide bond is hydrogen-bonded to the amide hydrogen atom of the amino acid four residues farther along the chain in the direction of the C-terminus (Figure 3-4). Within an α helix, all the backbone amino and carboxyl groups are hydrogen-bonded to one another except at the very beginning and end of the helix. This periodic

FIGURE 3-4 The α helix, a common secondary structure in proteins. The polypeptide backbone (seen as a ribbon) is folded into a spiral that is held in place by hydrogen bonds between backbone oxygen and hydrogen atoms. Only hydrogens involved in bonding are shown. The outer surface of the helix is covered by the side-chain R groups (green).

arrangement of bonds confers an amino-to-carboxy-terminal directionality on the helix because all the hydrogen bond acceptors (i.e., the carbonyl groups) have the same orientation (pointing in the downward direction in Figure 3-4), resulting in a structure in which there is a complete turn of the spiral every 3.6 residues. An α helix 36 amino acids long has 10 turns of the helix and is 5.4 nm long (0.54 nm/turn).

The stable arrangement of hydrogen-bonded amino acids in the α helix holds the backbone in a straight, rodlike cylinder from which the side chains point outward. The relative hydrophobic or hydrophilic quality of a particular helix within a protein is determined entirely by the characteristics of the side chains. In water-soluble proteins, hydrophilic helices tend to be found on the outside surfaces, where they can interact with the aqueous environment, whereas hydrophobic helices tend to be buried within the core of the folded protein. The amino acid proline is usually not found in α helices because the covalent bonding of its amino group with a carbon in the side chain prevents its participation in stabilizing the backbone through normal hydrogen bonding. While the classic α helix is the most intrinsically stable and most common helical form in proteins, there are variations, such as more tightly or loosely twisted helices. For example, in a specialized helix called a coiled coil (described several sections farther on), the helix is more tightly wound (3.5 residues and 0.51 nm per turn).

The β Sheet Another type of secondary structure, the β sheet, consists of laterally packed β strands. Each β strand is a short (5- to 8-residue), nearly fully extended polypeptide segment. Unlike in the α helix, where hydrogen bonds occur between the amino and carboxyl groups in the backbone between nearly adjacent residues, hydrogen bonds in the β sheet occur between backbone atoms in separate, but adjacent, β strands and are oriented perpendicularly to the chains of backbone atoms (Figure 3-5a). These distinct β strands may be either within a single polypeptide chain, with short or long loops between the β strand segments, or on different polypeptide chains in a protein composed of multiple polypeptides. Figure 3-5b shows how two or more β strands align into adjacent rows, forming a nearly two-dimensional β pleated sheet (or simply *pleated sheet*), in which hydrogen bonds within the plane of the sheet hold the β strands together as the side chains stick out above and below the plane. Like α helices, β strands have a directionality defined by the orientation of the peptide bond. Therefore, in a pleated sheet, adjacent β strands can be oriented in the same (parallel) or alternating opposite (antiparallel) directions with respect to each other. In Figure 3-5a, you can see that the N-to-C orientations of the chains, indicated by arrows, alternate directions between adjacent chains, signifying an antiparallel sheet. In some proteins, β sheets form the floor of a binding pocket or a hydrophobic core; in proteins embedded in membranes the β sheets curve around and form a hydrophilic central pore through which ions and small molecules may flow (see Chapter 11).

β Turns Composed of four residues, β turns are located on the surface of a protein, forming sharp bends that reverse the

(b) Side view

FIGURE 3-5 The β sheet, another common secondary structure in proteins. (a) Top view of a simple three-stranded β sheet with antiparallel β strands, as indicated by the arrows that represent the N-to-C orientations of the chains. The stabilizing hydrogen bonds between the β strands are indicated by green dashed lines. (b) Side view of a β sheet. The projection of the R groups (green) above and below the plane of the sheet is obvious in this view. The fixed bond angles in the polypeptide backbone produce a pleated contour.

direction of the polypeptide backbone, often toward the protein's interior. These short, U-shaped secondary structures are often stabilized by a hydrogen bond between their end residues (Figure 3-6). Glycine and proline are commonly present in turns. The lack of a large side chain in glycine and

FIGURE 3-6 Structure of a β turn. Composed of four residues, β turns reverse the direction of a polypeptide chain (180° U-turn). The C_α carbons of the first and fourth residues are usually <0.7 nm apart, and those residues are often linked by a hydrogen bond. β turns facilitate the folding of long polypeptides into compact structures.

FIGURE 3-7 Oil drop model of protein folding.

The hydrophobic residues (blue) of a polypeptide chain tend to cluster together, somewhat like an oil drop, on the inside, or core, of a folded protein, driven away from the aqueous surroundings by the hydrophobic effect (see Chapter 2). Charged and uncharged polar side chains (red) appear on the protein's surface, where they can form stabilizing interactions with surrounding water and ions.

the presence of a built-in bend in proline allow the polypeptide backbone to fold into a tight U shape. β turns help large proteins to fold into highly compact structures. There are six types of well-defined turns, their detailed structures depending on the arrangement of H-bonding interactions. A polypeptide backbone also may contain longer bends, or loops. In contrast with tight β turns, which exhibit just a few well-defined conformations, longer loops can have many different conformations.

Tertiary Structure Is the Overall Folding of a Polypeptide Chain

Tertiary structure refers to the overall conformation of a polypeptide chain—that is, the three-dimensional arrangement of all its amino acid residues. In contrast with secondary structures, which are stabilized only by hydrogen bonds, tertiary structure is primarily stabilized by hydrophobic interactions between nonpolar side chains, together with hydrogen bonds involving polar side chains and backbone amino and carboxyl groups. These stabilizing forces compactly hold together elements of secondary structure— α helices, β strands, turns, and coils. Because the stabilizing interactions are often weak, however, the tertiary structure of a protein is not rigidly fixed but undergoes continual, minute fluctuations, and some segments within the tertiary structure of a protein can be so very mobile they are considered to be disordered—that is, lacking well-defined, stable, three-dimensional structure. This variation in structure has important consequences for the function and regulation of proteins.

Chemical properties of amino acid side chains help define tertiary structure. **Disulfide bonds** between the side chains of cysteine residues in some proteins covalently link regions of proteins, thus restricting the proteins' flexibility and increasing the stability of their tertiary structures. Amino acids with charged hydrophilic polar side chains tend to be on the outer surfaces of proteins; by interacting with water, they help to make proteins soluble in aqueous solutions and can form noncovalent interactions with other water-soluble molecules, including other proteins. In contrast, amino acids with hydrophobic nonpolar side chains are usually sequestered away from the water-facing surfaces of a protein, in many cases forming a water-insoluble central core. This observation led to what's known as the "oil drop model" of

protein conformation because of the relatively hydrophobic, or "oily," core of a protein (Figure 3-7). Uncharged hydrophilic polar side chains are found on both the surface and inner core of proteins.

Proteins usually fall into one of three broad structural categories, based on their tertiary structure: globular proteins, fibrous proteins, and integral membrane proteins. *Globular proteins* are generally water-soluble, compactly folded structures, often but not exclusively spheroidal, that comprise a mixture of secondary structures (see the structure of myoglobin, below). *Fibrous proteins* are large, elongated, often stiff molecules. Some fibrous proteins are composed of a long polypeptide chain comprising many tandem copies of a short amino acid sequence that forms a single repeating secondary structure (see the structure of collagen, the most abundant protein in mammals, in Figure 20-24). Other fibrous proteins are composed of repeating globular protein subunits, such as the helical array of G-actin protein monomers that forms the F-actin microfilaments (see Chapter 17). Fibrous proteins, which often aggregate into large multiprotein fibers that do not readily dissolve in water, usually play a structural role or participate in cellular movements. *Integral membrane proteins* are embedded within the phospholipid bilayer of the membranes that enclose cells and organelles (see Chapter 10). The three broad categories of proteins noted here are not mutually exclusive—some proteins are made up of combinations of two or even all three categories.

Different Ways of Depicting the Conformation of Proteins Convey Different Types of Information

The simplest way to represent three-dimensional protein structure is to trace the course of the backbone atoms, sometimes only the C_α atoms, with a solid line (called a C_α trace, Figure 3-8a); the most complex model shows every atom (Figure 3-8b). The former shows the overall fold of the polypeptide chain without consideration of the amino acid side chains; the latter, a ball-and-stick model (with balls representing atoms and sticks representing bonds), details the interactions between side-chain atoms, including those that stabilize the protein's conformation and interact with other

FIGURE 3-8 Four ways to visualize protein structure. Shown here are four distinct methods for representing the structure of a protein called ras, a monomeric (single polypeptide chain) protein that binds to guanosine diphosphate (GDP, depicted in blue). (a) The C_α backbone trace demonstrates how the polypeptide is tightly packed into a small volume. (b) A ball-and-stick representation reveals the location of all atoms. (c) A ribbon representation emphasizes how β strands (light blue) and α helices (red) are organized in the protein. Note the turns and loops connecting pairs of helices and strands. (d) A model of the water-accessible surface reveals the numerous lumps, bumps, and crevices on the protein surface. Regions of positive charge are shaded purple; regions of negative charge are shaded red.

molecules as well as the atoms of the backbone. Even though both views are useful, the elements of secondary structure are not always easily discerned in them. Another type of representation uses common shorthand symbols for depicting secondary structure—for example, coiled ribbons or solid cylinders for α helices, flat ribbons or arrows for β strands, and flexible thin strands for β turns, coils, and loops (Figure 3-8c). In a variation of the basic ribbon diagram, ball-and-stick or space-filling models of all or only a subset of side chains can be attached to the backbone ribbon. In this way, side chains that are of interest can be visualized in the context of the secondary structure that is especially clearly represented by the ribbons.

However, none of these three ways of representing protein structure conveys much information about the protein surface, which is of interest because it is where other molecules usually bind to a protein. Computer analysis can identify the surface atoms that are in contact with the watery environment. On this water-accessible surface, regions having a common chemical character, such as, hydrophobicity or hydrophilicity, and charge characteristics, such as positive (basic) or negative (acidic) side chains, can be indicated by coloring (Figure 3-8d). Such models reveal the topography of the protein surface and the distribution of charge, both important features of binding sites, as well as clefts in the surface where small molecules bind. This view represents a protein as it is “seen” by another molecule.

Structural Motifs Are Regular Combinations of Secondary Structures

A particular combination of two or more secondary structures that form a distinct three-dimensional structure is called a **structural motif** when it appears in multiple proteins. A structural motif is often, but not always, associated with a specific function. Any particular structural motif will frequently perform a common function in different proteins, such as binding to a particular ion or small molecule, for example, calcium or ATP.

One common structural motif is the α helix–based coiled coil, or heptad repeat. Many proteins, including fibrous proteins and DNA-regulating proteins called transcription factors (see Chapter 7), assemble into dimers or trimers by using a coiled-coil motif, in which α helices from two, three, or even four separate polypeptide chains coil about one another—resulting in a coil of coils; hence the name (Figure 3-9a). The individual helices bind tightly to one another because each helix has a strip of aliphatic (hydrophobic, but not aromatic) side chains (leucine valine, etc.) running along one side of the helix that interacts with a similar strip in the adjacent helix, thus sequestering the hydrophobic groups away from water and stabilizing the assembly of multiple independent helices. These hydrophobic strips are generated along only one side of the helix because the primary structure of each helix is composed of repeating seven-amino-acid

FIGURE 3-9 Motifs of protein secondary structure. (a) The parallel two-stranded coiled-coil motif (left) is characterized by two α helices wound around each other. Helix packing is stabilized by interactions between hydrophobic side chains (red and blue) present at regular intervals along each strand and found along the seam of the intertwined helices. Each α helix exhibits a characteristic heptad repeat sequence with a hydrophobic residue often, but not always, at positions 1 and 4, as indicated. The coiled-coil nature of this structural motif is more apparent in long coiled coils containing many such motifs (right). (b) An EF hand, a type of helix-loop-helix motif, consists of two helices connected by a short loop in a specific conformation. This structural motif is common to many proteins, including many

calcium-binding and DNA-binding regulatory proteins. In calcium-binding proteins such as calmodulin, oxygen atoms from five residues in the acidic glutamate- and aspartate-rich loop and one water molecule form ionic bonds with a Ca^{2+} ion. (c) The zinc-finger motif is present in many DNA-binding proteins that help regulate transcription. A Zn^{2+} ion is held between a pair of β strands (blue) and a single α helix (red) by a pair of cysteine residues and a pair of histidine residues. The two invariant cysteine residues are usually at positions 3 and 6, and the two invariant histidine residues are at positions 20 and 24 in this 25-residue motif. [See A. Lewit-Bentley and S. Rety, 2000, *Curr. Opin. Struc. Biol.* **10**:637–643; S. A. Wolfe, L. Nekludova, and C. O. Pabo, 2000, *Ann. Rev. Biophys. Biomol. Struc.* **29**:183–212.]

units, called heptads, in which the side chains of the first and fourth residues are aliphatic and the other side chains are often hydrophilic (Figure 3-9a). Because hydrophilic side chains extend from one side of the helix and hydrophobic side chains extend from the opposite side, the overall helical structure is **amphipathic**. Because leucine frequently appears in the fourth positions and the hydrophobic side chains merge together like the teeth of a zipper, these structural motifs are also called **leucine zippers**.

Many other structural motifs contain α helices. A common calcium-binding motif called the **EF hand** contains two short helices connected by a loop (Figure 3-9b). This structural motif, one of several **helix-turn-helix** structural motifs, is found in more than 100 proteins and is used for sensing the calcium levels in cells. The binding of a Ca^{2+} ion to oxygen atoms in conserved residues in the loop depends on the concentration of Ca^{2+} and often induces a conformational change in the protein, altering its activity. Thus calcium concentrations can directly control proteins' structures and functions. Somewhat different helix-turn-helix and basic **helix-loop-helix** (bHLH) structural motifs are used for protein binding to DNA and consequently the regulation of

gene activity (see Chapter 7). Yet another structural motif commonly found in proteins that bind RNA or DNA is the **zinc finger**, which contains three secondary structures—an α helix and two β strands with an antiparallel orientation—that form a fingerlike bundle held together by a zinc ion (Figure 3-9c).

The relationship between the primary structure of a polypeptide chain and the structural motifs into which it folds is not always straightforward. The amino acid sequences responsible for any given structural motif may be very similar to one another. In other words, a common *sequence motif* can result in a common structural motif. This is the case for the heptad repeats that form coiled coils. However, it is possible for seemingly unrelated amino acid sequences to fold into a common structural motif, so it is not always possible to predict which amino acids sequences will fold into a given structural motif. Conversely, it is possible that a commonly occurring sequence motif does not fold into a well-defined structural motif. Sometimes short sequence motifs that have an unusual abundance of a particular amino acid, for example, proline or aspartate or glutamate, are called “domains”; however, these and other short contiguous segments are

more appropriately called sequence motifs than domains, which has a distinct meaning that is defined below.

We will encounter numerous additional motifs in later discussions of other proteins in this and other chapters. The presence of the same structural motif in different proteins with similar functions clearly indicates that these useful combinations of secondary structures have been conserved in evolution.

Domains Are Modules of Tertiary Structure

Distinct regions of protein structure often are referred to as **domains**. There are three main classes of protein domains: functional, structural, and topological. A *functional domain* is a region of a protein that exhibits a particular activity characteristic of the protein, usually even when isolated from the rest of the protein. For instance, a particular region of a protein may be responsible for its catalytic activity (e.g., a kinase domain that covalently adds a phosphate group to another molecule) or binding ability (e.g., a DNA-binding domain or a membrane-binding domain). Functional domains are often identified experimentally by whittling down a protein to its smallest active fragment with the aid of **proteases**, enzymes that cleave one or more peptide bonds in a target polypeptide. Alternatively, the DNA encoding a protein can be modified so that when the modified DNA is used to generate a protein, only a particular region, or domain, of the full-length protein is made. Thus it is possible to determine if specific

parts of a protein are responsible for particular activities exhibited by the protein. Indeed, functional domains are often also associated with corresponding structural domains.

A *structural domain* is a region ~40 or more amino acids in length, arranged in a single, stable, and distinct structure often comprising one or more secondary structures. Structural domains often can fold into their characteristic structures independently of the rest of the protein in which they are embedded. As a consequence, distinct structural domains can be linked together—sometimes by short or long spacers—to form a large, multidomain protein. Each of the polypeptide chains in the trimeric flu virus hemagglutinin, for example, contains a globular domain and a fibrous domain (Figure 3-10a). Like structural motifs (composed of secondary structures), structural domains are incorporated as modules into different proteins. The modular approach to protein architecture is particularly easy to recognize in large proteins, which tend to be mosaics of different domains that confer distinct activities and thus can perform different functions simultaneously. As many as 75 percent of the proteins in eukaryotes have multiple structural domains. Structural domains frequently are also functional domains in that they can have an activity independent of the rest of the protein.

The epidermal growth factor (EGF) domain is a structural domain present in several proteins (Figure 3-11). EGF is a small, soluble peptide hormone that binds to cells in the embryo and in skin and connective tissue in adults, causing them

FIGURE 3-10 Tertiary and quaternary levels of structure. The protein pictured here, hemagglutinin (HA), is found on the surface of the influenza virus. This long, multimeric molecule has three identical subunits, each composed of two polypeptide chains, HA₁ and HA₂. (a) Tertiary structure of each HA subunit comprises the folding of its helices and strands into a compact structure that is 13.5 nm long and divided into two domains. The membrane-distal domain (silver) is folded into a globular conformation. The membrane-proximal domain (gold) has a fibrous, stemlike conformation owing to the alignment of two long α helices (cylinders) of HA₂ with β strands in HA₁. Short turns and longer loops, often at the surface of the molecule, connect the helices and strands in each chain. (b) Quaternary structure of HA is stabilized by lateral interactions between the long helices (cylinders) in the fibrous domains of the three subunits (gold, blue, and green), forming a triple-stranded coiled-coil stalk. Each of the distal globular domains in HA binds sialic acid (red) on the surface of target cells. Like many membrane proteins, HA contains several covalently linked carbohydrate chains (not shown).

FIGURE 3-11 Modular nature of protein domains. Epidermal growth factor (EGF) is generated by proteolytic cleavage of a precursor protein containing multiple EGF domains (green) and a membrane-spanning domain (blue). The EGF domain is also present in the Neu protein and in tissue plasminogen activator (TPA). These proteins also contain other widely distributed domains, indicated by shape and color. [Adapted from I. D. Campbell and P. Bork, 1993, *Curr. Opin. Struc. Biol.* 3:385.]

to divide. It is generated by proteolytic cleavage (breaking of a peptide bond) between repeated EGF domains in the EGF precursor protein, which is anchored in the cell membrane by a membrane-spanning domain. EGF domains with sequences similar to, but not identical to, those in the EGF peptide hormone are present in other proteins and can be liberated by proteolysis. These proteins include tissue plasminogen activator (TPA), a protease that is used to dissolve blood clots in heart attack victims; Neu protein, which takes part in embryonic differentiation; and Notch protein, a receptor protein in the plasma membrane that functions in developmentally important signaling (see Chapter 16). Besides the EGF domain, these proteins have other domains in common with other proteins. For example, TPA possesses a trypsin domain, a functional domain in some proteases. It is estimated that there are about 1000 different types of structural domains in all proteins. Some of these are not very common, whereas others are found in many different proteins. Indeed, by some estimates only nine major types of structural domains account for as much as a third of all the structural domains in all proteins. Structural domains can be recognized in proteins whose structures have been determined by x-ray crystallography or nuclear magnetic resonance (NMR) analysis or in images captured by electron microscopy.

Regions of proteins that are defined by their distinctive spatial relationships to the rest of the protein are *topological domains*. For example, some proteins associated with cell-surface membranes can have a part extending inward into the cytoplasm (cytoplasmic domain), a part embedded within the phospholipid bilayer membrane (membrane-spanning domain), and a part extending outward into the extracellular space (extracellular domain). Each of these can comprise one or more structural and functional domains.

In Chapter 6 we consider the mechanism by which the gene segments that correspond to domains became shuffled in the course of evolution, resulting in their appearance in many proteins. Once a functional, structural, or topological domain has been identified and characterized in one protein,

it is possible to use that information to search for similar domains in other proteins and to suggest potentially similar functions for those domains in those proteins.

Multiple Polypeptides Assemble into Quaternary Structures and Supramolecular Complexes

Multimeric proteins consist of two or more polypeptide chains, which in this context are referred to as subunits. A fourth level of structural organization, **quaternary structure**, describes the number (stoichiometry) and relative positions of the subunits in multimeric proteins. Flu virus hemagglutinin, for example, is a trimer of three identical subunits (homotrimer) held together by noncovalent bonds (see Figure 3-10b). Other multimeric proteins can be composed of various numbers of identical (homomeric) or different (heteromeric) subunits. Hemoglobin, the oxygen-carrying molecule in blood, is an example of a heteromeric multimeric protein. It has two copies each of two different polypeptide chains (discussed below). Often, the individual monomer subunits of a multimeric protein cannot function normally unless they are assembled into the multimeric protein. In some cases, assembly into a multimeric protein permits proteins that act sequentially in a pathway to increase their efficiency of operation owing to their juxtaposition in space, a phenomenon referred to as “metabolic coupling.” Classic examples of this coupling are fatty acid synthases, the enzymes in fungi that synthesize fatty acids, and the polyketide synthases, the large multiprotein complexes in bacteria that synthesize a diverse set of pharmacologically relevant molecules called polyketides, including the antibiotic erythromycin.

The highest level in the hierarchy of protein structure is the association of proteins into supramolecular complexes. Typically, such structures are very large, in some cases exceeding 1 MDa in mass, approaching 30–300 nm in size, and containing tens to hundreds of polypeptide chains and sometimes other biopolymers such as nucleic acids. The capsid that encases the nucleic acids of the viral genome is an example of a supramolecular complex with a structural function. The bundles of cytoskeletal filaments that support and give shape to the plasma membrane are another example. Other supramolecular complexes act as molecular machines, carrying out the most complex cellular processes by integrating multiple proteins, each with distinct functions, into one large assembly. For example, a transcriptional machine is responsible for synthesizing messenger RNA (mRNA) using a DNA template. This transcriptional machine, the operational details of which are discussed in Chapter 4, consists of RNA polymerase, itself a multimeric protein, and at least 50 additional components, including general transcription factors, promoter-binding proteins, helicase, and other protein complexes (Figure 3-12). Ribosomes, also discussed in Chapter 4, are complex multiprotein and multi-nucleic acid machines that synthesize proteins. One of the most complex multiprotein assemblies is the nuclear pore, a structure that allows communication and passage of macromolecules between nucleoplasm and cytoplasm

FIGURE 3-12 A macromolecular machine: the transcription-initiation complex. The core RNA polymerase, general transcription factors, a mediator complex containing about 20 subunits, and other protein complexes not depicted here assemble at a promoter in DNA. The polymerase carries out transcription of DNA; the associated proteins are required for initial binding of polymerase to a specific promoter. The multiple components function together as a machine.

(see Chapter 14). It is composed of multiple copies of about 30 distinct proteins and forms an assembly with an estimated mass of around 50 megadaltons. The fatty acid synthases and polyketide synthases referred to above are also supramolecular machines.

Members of Protein Families Have a Common Evolutionary Ancestor

Studies of myoglobin and hemoglobin, the oxygen-carrying proteins in muscle and red blood cells, respectively, provided early evidence that a protein's function derives from its three-dimensional structure, which in turn is specified by amino acid sequence. X-ray crystallographic analysis showed that the three-dimensional structures of myoglobin (a monomer) and the α and β subunits of hemoglobin (a $\alpha_2\beta_2$ tetramer) are remarkably similar. Sequencing of myoglobin and the hemoglobin subunits revealed that many identical or chemically similar residues are found in equivalent positions throughout the primary structures of both proteins. A mutation in the gene encoding the β chain that results in the substitution of a valine for a glutamic acid disturbs the folding and function of hemoglobin and causes sickle-cell anemia.

Similar comparisons between other proteins conclusively confirmed the relation between the amino acid sequence, three-dimensional structure, and function of proteins. Use of sequence comparisons to deduce protein function has expanded substantially in recent years as the genomes of more and more organisms have been sequenced. While this

comparative approach is very powerful, caution must always be exercised when attributing to one protein, or a part of a protein, a similar function or structure to another based only on amino acid sequence similarities. There are examples in which proteins with similar overall structures display different functions and cases in which functionally unrelated proteins with dissimilar amino acid sequences nevertheless have very similar folded tertiary structures, as will be explained below. Nevertheless, in many cases such comparisons provide important insights into protein structure and function.

The molecular revolution in biology during the last decades of the twentieth century created a new scheme of biological classification based on similarities and differences in the amino acid sequences of proteins. Proteins that have a common ancestor are referred to as **homologs**. The main evidence for **homology** among proteins, and hence for their common ancestry, is similarity in their sequences, which is often also reflected in similar structures. We can describe homologous proteins as belonging to a “family” and can trace their lineage from comparisons of their sequences. Generally, more closely related proteins will exhibit greater sequence similarity than more distantly related proteins because, over evolutionary time, mutations accumulate in the genes encoding these proteins. The folded three-dimensional structures of homologous proteins can be similar even if parts of their primary structure show little evidence of sequence homology. Initially, proteins with relatively high sequence similarities (>50 percent exact matches, or “identities”) and related functions or structures were defined as an evolutionarily related *family*, while a *superfamily* encompassed two or more families in which the interfamilial sequences matched less well (~30–40 percent identities) than within one family. It is generally thought that proteins with 30 percent sequence identity are likely to have similar three-dimensional structures; however, such high sequence identity is not required for proteins to share similar structures. Recently, revised definitions of *family* and *superfamily* have been proposed, in which a family comprises proteins with a clear evolutionary relationship (>30 percent identity or additional structural and functional information showing common descent but <30 percent identity), while a superfamily comprises proteins with only a probable common evolutionary origin—for example, lower percent sequence identities but one or more common motifs or domains.

The kinship among homologous proteins is most easily visualized by a tree diagram based on sequence analyses. For example, the amino acid sequences of globins—the proteins hemoglobin and myoglobin and their relatives from bacteria, plants, and animals—suggest that they evolved from an ancestral monomeric, oxygen-binding protein (Figure 3-13). With the passage of time, the gene for this ancestral protein slowly changed, initially diverging into lineages leading to animal and plant globins. Subsequent changes gave rise to myoglobin, the monomeric oxygen-storing protein in muscle, and to the α and β subunits of the tetrameric hemoglobin molecule ($\alpha_2\beta_2$) of the vertebrate circulatory system.

FIGURE 3-13 Evolution of the globin protein family. Left: A primitive monomeric oxygen-binding globin is thought to be the ancestor of modern-day blood hemoglobins, muscle myoglobins, and plant leghemoglobins. Sequence comparisons have revealed that evolution of the globin proteins parallels the evolution of animals and plants. Major junctions occurred with the divergence of plant globins from animal globins and of myoglobin from hemoglobin. Later gene

duplication gave rise to the α and β subunits of hemoglobin. Right: Hemoglobin is a tetramer of two α and two β subunits. The structural similarity of these subunits with leghemoglobin and myoglobin, both of which are monomers, is evident. A heme molecule (red) noncovalently associated with each globin polypeptide is directly responsible for oxygen-binding in these proteins. [Adapted from R. C. Hardison, 1996, *Proc. Nat'l Acad. Sci. USA* 93:5675.]

KEY CONCEPTS of Section 3.1

Hierarchical Structure of Proteins

- Proteins are linear polymers of amino acids linked together by peptide bonds. A protein can have a single polypeptide chain or multiple polypeptide chains. The primary structure of a polypeptide chain is the sequence of covalently linked amino acids that compose the chain. Various, mostly noncovalent interactions between amino acids in the linear sequence stabilize a protein's specific folded three-dimensional structure, or conformation.
- The α helix, β strand and sheet, and β turn are the most prevalent elements of protein secondary structure. Secondary structures are stabilized by hydrogen bonds between atoms of the peptide backbone (see Figures 3-4 through 3-6).
- Protein tertiary structure results from hydrophobic interactions between nonpolar side groups and hydrogen bonds and ionic interactions involving polar side groups and the polypeptide backbone. These interactions stabilize folding of the protein, including its secondary structural elements, into an overall three-dimensional arrangement.
- Certain combinations of secondary structures give rise to different structural motifs, which are found in a variety of proteins and are often associated with specific functions (see Figure 3-9).

- Proteins often contain distinct domains, independently folded regions with characteristic structural, functional, and topological properties (see Figure 3-10).
- The incorporation of domains as modules in different proteins in the course of evolution has generated diversity in protein structure and function.
- The number and organization of individual polypeptide subunits in multimeric proteins define their quaternary structure.
- Cells contain large supramolecular assemblies, sometimes called molecular machines, in which all the necessary participants in complex cellular processes (e.g., DNA, RNA, and protein synthesis; photosynthesis; signal transduction) are bound together.
- Homologous proteins are proteins that evolved from a common ancestor and thus have similar sequences, structures, and functions. They can be classified into families and superfamilies.

3.2 Protein Folding

As noted above, when it comes to the architecture of proteins, "form follows function." Thus it is essential that when a polypeptide is synthesized with its particular amino acid

sequence, it folds into the proper three-dimensional conformation with the appropriate secondary, tertiary, and possibly quaternary structure if it is to fulfill its biological role within or outside cells. How is a protein with a proper sequence generated? A polypeptide chain is synthesized by a complex process called **translation**, which occurs in the cytoplasm on a large protein–nucleic acid complex called a **ribosome**. During translation, a sequence of **messenger RNA (mRNA)** serves as a template from which the assembly of a corresponding amino acid sequence is directed. The mRNA is initially generated by a process called **transcription**, whereby a nucleotide sequence in DNA is converted, by transcriptional machinery in the nucleus, into a sequence of mRNA. The intricacies of transcription and translation are considered in Chapter 4. Here we describe the key determinants of the proper folding of a newly formed or forming (nascent) polypeptide chain as it emerges from the ribosome.

Planar Peptide Bonds Limit the Shapes into Which Proteins Can Fold

A critical structural feature of polypeptides that limits how the chain can fold is the planar peptide bond. Figure 3-3 illustrates the amide group in peptide bonds in a polypeptide chain. Because the peptide bond itself behaves partially like a double bond,

the carbonyl carbon and amide nitrogen and those atoms directly bonded to them must all lie in a fixed plane (Figure 3-14);

FIGURE 3-14 Rotation between planar peptide groups in proteins. Rotation about the C_{α} –amino nitrogen bond (the Φ angle) and the C_{α} –carbonyl carbon bond (the Ψ angle) permits polypeptide backbones, in principle, to adopt a very large number of potential conformations. However, steric restraints due to the structure of the polypeptide backbone and the properties of the amino acid side chains dramatically restrict the potential conformations that any given protein can assume.

there is no rotation possible about the peptide bond itself. As a consequence, the only flexibility in a polypeptide chain backbone, allowing it to twist and turn—and thus fold into different three-dimensional shapes—is rotation of the fixed planes of adjacent peptide bonds with respect to one another about two bonds: the C_{α} –amino nitrogen bond (rotational angle called Φ) and the C_{α} –carbonyl carbon bond (rotational angle called Ψ).

Yet a further constraint on the potential conformations that a polypeptide backbone chain can adopt is the fact that only a limited number of Φ and Ψ angles are possible because for most Φ and Ψ angles, the backbone or side chain atoms would come too close to one another and thus the associated conformation would be highly unstable or even physically impossible to achieve.

The Amino Acid Sequence of a Protein Determines How It Will Fold

While the constraints of backbone bond angles seem very restrictive, any polypeptide chain containing only a few residues could, in principle, still fold into many conformations. For example, if the Φ and Ψ angles were limited to only eight combinations, an n -residue-long peptide would potentially have 8^n conformations; for even a small polypeptide of only 10 residues, that's about 8.6 million possible conformations! In general, however, any particular protein adopts only one or just a few very closely related conformations called the *native state*; for the vast majority of proteins, the native state is the most stably folded form of the molecule and the one that permits it to function normally. In thermodynamic terms, the native state is usually the conformation with the lowest free energy (G) (see Chapter 2).

What features of proteins limit their folding from very many potential conformations to just one? The properties of the side chains (e.g., size, hydrophobicity, ability to form hydrogen and ionic bonds), together with their particular sequence along the polypeptide backbone, impose key restrictions. For example, a large side chain such as that of tryptophan might sterically block one region of the chain from packing closely against another region, whereas a side chain with a positive charge such as arginine might attract a segment of the polypeptide that has a complementary negatively charged side chain (e.g., aspartic acid). Another example we have already discussed is the effect of the aliphatic side chains in heptad repeats in promoting the association of helices and the consequent formation of coiled coils. Thus a polypeptide's primary structure determines its secondary, tertiary, and quaternary structures.

The initial evidence that the information necessary for a protein to fold properly is encoded in its amino acid sequence came from in vitro studies on the refolding of purified proteins, especially the Nobel Prize–winning studies in the 1960s by Christian Anfinsen of the refolding of ribonuclease A, an enzyme that cleaves RNA. Others had previously shown that various chemical and physical perturbations can disrupt the weak noncovalent interactions that stabilize the native conformation of a protein, leading to the loss of

its normal tertiary structure. The process by which a protein's structure (and this can include secondary as well as tertiary structure) is disrupted is called **denaturation**. Denaturation can be induced by thermal energy from heat, extremes of pH that alter the charges on amino acid side chains, and exposure to *denaturants* such as urea or guanidine hydrochloride at concentrations of 6–8 M, all of which disrupt structure-stabilizing noncovalent interactions. Treatment with reducing agents, such as β -mercaptoethanol, that break disulfide bonds can further destabilize disulfide-containing proteins. Under such unfolding or denaturing conditions, a population of uniformly folded molecules is destabilized and converted into a collection of many unfolded, or denatured, molecules that have many different non-native and biologically inactive conformations. As we have seen, a large number of possible non-native conformations exist (e.g., $8^n - 1$).

The spontaneous unfolding of proteins under denaturing conditions is not surprising, given the substantial increase in entropy that accompanies the denatured protein assuming many non-native conformations. What is striking, however, is that when a pure sample of a single type of unfolded protein in a test tube is shifted back very carefully to normal conditions (body temperature, normal pH levels, reduction in the concentration of denaturants), some denatured polypeptides can spontaneously refold into their native, biologically active states as in Anfinsen's experiments. This kind of refolding experiment, as well as studies that show synthetic proteins made chemically can fold properly, showed that the information contained in a protein's primary structure can be sufficient to direct correct refolding. Newly synthesized proteins appear to fold into their proper conformations just as denatured proteins do. The observed similarity in the folded, three-dimensional structures of proteins with similar amino acid sequences, noted in Section 3.1, provided additional evidence that the primary sequence also determines protein folding *in vivo*. It appears that formation of secondary structures and structural motifs occurs early in the folding process, followed by assembly of more complex structural domains, which then associate into more complex tertiary and quaternary structures (Figure 3-15).

Folding of Proteins in Vivo Is Promoted by Chaperones

The conditions of refolding of a purified, denatured protein in a test tube differ markedly from the conditions under which a newly synthesized polypeptide folds in a cell. The presence of other biomolecules, including many other proteins at very high concentration (~ 300 mg/ml in mammalian cells), some of which are themselves nascent and in the process of folding, can potentially interfere with the autonomous, spontaneous folding of a protein. Furthermore, although protein folding into the native state can occur *in vitro*, this does not happen for all unfolded molecules in a timely fashion. Given such impediments, cells require a faster, more efficient mechanism for folding proteins into their correct shapes than sequence alone provides. Without

FIGURE 3-15 Hypothetical protein-folding pathway. Folding of a monomeric protein follows the structural hierarchy of primary (a) $\rightarrow$ secondary (b–d) $\rightarrow$ tertiary (e) structure. Formation of small structural motifs (c) appears to precede formation of domains (d) and the final tertiary structure (e).

such help, cells might waste much energy in the synthesis of improperly folded, nonfunctional proteins, which would have to be destroyed to prevent their disrupting cell function. Cells clearly have such mechanisms since more than 95 percent of the proteins present within cells have been shown to be in their native conformations. The explanation for the cell's remarkable efficiency in promoting proper protein folding is that cells make a set of proteins, called **chaperones**, that facilitate proper folding of nascent proteins.

The importance of chaperones is highlighted by the observations that many are evolutionarily conserved. Chaperones are found in all organisms from bacteria to humans, and some are homologs with high sequence similarity that use almost identical mechanisms to assist protein folding.

Chaperones use ATP binding, ATP hydrolysis to ADP, and exchange of a new ATP molecule for the ADP to induce a series of conformational changes essential for their function. Chaperones can fold newly made proteins into functional conformations, refold misfolded or unfolded proteins into functional conformations, disassemble potentially toxic protein aggregates that form due to protein misfolding, and assemble and dismantle large multiprotein complexes. Chaperones, which in eukaryotes are located in every cellular compartment and organelle, bind to the target proteins whose folding they will assist. There are several different classes of chaperones with distinct structures that all use ATP binding and hydrolysis in a variety of ways to facilitate folding. These include (1) enhancing the binding of protein substrates and (2) switching the conformation of the chaperones. The ATP-dependent conformational switch is used (1) to optimize folding after one substrate is folded, (2) to return the chaperone to its initial state so that it is available to help fold another molecule, and (3) to set the time permitted for refolding, which can be determined by the rate of ATP hydrolysis.

Two general families of chaperones have been identified:

- **Molecular chaperones**, which bind to a short segment of a protein substrate and stabilize unfolded or partly folded proteins, thereby preventing these proteins from aggregating and being degraded;
- **Chaperonins**, which form small folding chambers into which all or part of an unfolded protein can be sequestered, giving it time and an appropriate environment to fold properly.

One reason that chaperones are needed for intracellular protein folding is that they help prevent aggregation of unfolded proteins. Unfolded and partly folded proteins tend to aggregate into large, often water-insoluble masses, from which it is extremely difficult for a protein to dissociate and then fold into its proper conformation. In part this aggregation is due to the exposure of hydrophobic side chains that have not yet had a chance to be buried in the inner core of the folded protein. These exposed hydrophobic side chains on different molecules will stick to one another, owing to the hydrophobic effect (see Chapter 2) and thus promote aggregation. The risk for such aggregation is especially high for newly synthesized proteins that have not yet completed their proper folding. Chaperones prevent aggregation by binding to the target polypeptide or sequestering it from other partially or fully unfolded proteins, thus giving the nascent protein time to fold properly.

Molecular Chaperones The heat-shock protein Hsp70 in the cytosol and its homologs (Hsp70 in the mitochondrial matrix, BiP in the endoplasmic reticulum, and DnaK in bacteria) are molecular chaperones. They were first identified by their rapid appearance after a cell has been stressed by heat shock (*Hsp* stands for “heat-shock protein”). Hsp70 and its homologs are the major chaperones in all organisms. When bound to ATP, the monomeric Hsp70 protein assumes an open form in which an exposed hydrophobic substrate binding pocket

transiently binds to exposed hydrophobic regions of an incompletely folded or partially denatured target protein and then rapidly releases this substrate as long as ATP is bound (step 1 in Figure 3-16a). Hydrolysis of the bound ATP causes the molecular chaperone to assume a closed form that binds its substrate protein much more tightly and this tighter binding appears to facilitate the target protein’s folding, in part by preventing it from aggregating with other unfolded proteins. The exchange of ATP for the protein-bound ADP causes a conformational change in the chaperone that releases the target protein. If the target is now properly folded, it cannot rebound to an Hsp70. If it remains at least partially unfolded, it can bind again to give it another chance to fold properly.

Additional proteins, such as the co-chaperone Hsp40 in eukaryotes (DnaJ in bacteria), help increase efficiency of Hsp70-mediated folding of many proteins by stimulating—together with the binding of substrate—the rate of hydrolysis of ATP by Hsp70/DnaK by 100- to 1000-fold (see step 2 in Figure 3-16a). Members of four different families of nucleotide exchange factors (e.g., GrpE in bacteria; BAG, HspBP, and Hsp110 families in eukaryotes) also interact with the Hsp70/DnaK, promoting the exchange of ATP for ADP. Multiple molecular chaperones are thought to bind all nascent polypeptide chains as they are being synthesized on ribosomes. In bacteria, 85 percent of the proteins are released from their chaperones and proceed to fold normally; an even higher percentage of proteins in eukaryotes follow this pathway.

The Hsp70 protein family is not the only class of molecular chaperones. Another distinct class of molecular chaperones is the Hsp90 family. Hsp90 family members are present in all organisms except archaea. In eukaryotes there are distinct Hsp90s located in different organelles and Hsp90 is one of the most abundant proteins in the cytosol (1–2 percent of total protein). Although the range of protein substrates of Hsp90 chaperones is not as broad as for some other chaperones, the Hsp90s are critically important in cells. They help cells cope with denatured proteins generated by stress (e.g., heat shock) and they ensure that some of their substrates, usually called “clients,” can be converted from an inactive to an active state or otherwise held in a functional conformation. In some cases the Hsp90s form a relatively stable complex with their clients until an appropriate signal causes their dissociation from the client, freeing the client to perform some regulated function in the cells. These clients include transcription factors, such as the receptors for the steroid hormones estrogen or testosterone that regulate sexual development and function by controlling the activities of many genes (see Chapter 7). Another type of Hsp90 client is enzymes called kinases, which control the activities of many proteins by phosphorylation (see Chapters 15 and 16). It is estimated that as many as 20 percent of all proteins in yeast are directly or indirectly influenced by the activities of Hsp90.

Unlike monomeric Hsp70, Hsp90 functions as a dimer in a cycle in which ATP binding, hydrolysis, and ADP release are coupled to major conformational changes and to binding, activation, and release of clients (Figure 3-16b). Although much about the mechanism of Hsp90 remains to be learned,

FIGURE 3-16 Molecular chaperone-mediated protein folding. (a) Hsp70. Many proteins fold into their proper three-dimensional structures with the assistance of Hsp70-like proteins. These molecular chaperones transiently bind to a nascent polypeptide as it emerges from a ribosome or to proteins that have otherwise unfolded. In the Hsp70 cycle, an unfolded protein substrate binds in rapid equilibrium to the open conformation of the substrate-binding domain (SBD, orange) of the monomeric Hsp70, to which an ATP (red oval) is bound in the nucleotide-binding domain (NBD, blue) (step 1). The substrate binding pocket is shown as a green patch on the substrate-binding domain. Co-chaperone accessory proteins (DnaJ/Hsp40) stimulate the hydrolysis of ATP to ADP (blue oval) and conformational change in Hsp70, resulting in the closed form, in which the substrate is locked into the SBD; here proper folding is facilitated (step 2). Exchange of ATP for the bound ADP, stimulated by other accessory co-chaperone proteins (GrpE/BAG1), converts the Hsp70 back to the open form (step 3), releasing the properly folded substrate (step 4).

(b) Hsp90. Hsp90 proteins are dimers, whose monomers contains an N-terminal NBD domain (blue), a central substrate (client) binding domain (SBD, orange), and a C-terminal dimerization domain (gray). The Hsp90 cycle begins when there is no nucleotide bound to the NBD and the dimer is in a very flexible, open (Y-shaped) configuration that can bind substrates (step 1). Rapid ATP binding leads to a slow conformational change in which the NBDs dimerize and the SBDs move together into a closed conformation (step 2). ATP hydrolysis results in folding of the client and client protein release (steps 3 and 4). The ADP-bound form of Hsp90 can adopt several conformations, including a highly compact form. Release of ADP regenerates the initial state, which can then interact with additional clients (step 4). [Part (b) modified from M. Taipale, D. F. Jarosz, and S. Lindquist, 2010, *Nat. Rev. Mol. Cell Biol.*, 11(7):515–528.]

it is clear that clients bind to the “open” conformation, that ATP binding leads to interaction of the ATP binding domains and formation of a “closed” conformation, and that hydrolysis of ATP plays an important role in activating some client proteins and their subsequent release from the Hsp90. We also know that there are at least 20 co-chaperones that can have profound effects on the activity of Hsp90, including ATPase activity and determining which proteins will be

clients (client specificity). Co-chaperones also can help coordinate the activities of Hsp90 and Hsp70. For example, Hsp70 can help begin the folding of a client that is then handed off by a co-chaperone to Hsp90 for additional processing. Hsp90 activity can also be influenced by its covalent modification by small molecules. Finally, Hsp90s can help cells recognize misfolded proteins that are unable to refold and facilitate their degradation by mechanisms discussed later in this chapter.

Thus, as part of the quality-control system in cells, chaperones can help properly fold proteins or facilitate the destruction of those that cannot fold properly.

Chaperonins The proper folding of a large variety of newly synthesized proteins also requires the assistance of another class of proteins, the chaperonins, also called Hsp60s. These huge cylindrical supramolecular assemblies are formed from two rings of oligomers. There are two distinct groups of chaperonins that differ somewhat in their structures, detailed molecular mechanisms, and locations. Group I chaperonins, found in prokaryotes, chloroplasts, and mitochondria, are composed of two rings, each having seven subunits that

interact with a homoheptameric co-chaperone “lid.” The bacteria group I chaperonin, known as GroEL/GroES, is shown in Figure 3-17a. In the bacterium *E. coli*, GroEL is thought to participate in the folding of about 10 percent of all proteins. Group II chaperonins, which are found in the cytosol of eukaryotic cells (e.g., TriC in mammals) and in archaea, can have eight to nine either homomeric or heteromeric subunits in each ring, and the “lid” function is incorporated in those subunits themselves—no separate lid is needed. It appears that ATP hydrolysis triggers the closing of the lid of group II chaperonins.

Figure 3-17b illustrates the GroEL/GroES cycle of protein folding. A partly folded or misfolded polypeptide <60 kD in

FOCUS ANIMATION: GroEL ATPase Cycle

FIGURE 3-17 Chaperonin-mediated protein folding. Proper folding of some proteins depends on chaperonins such as the prokaryotic group I chaperonin GroEL. (a) GroEL is a barrel-shaped complex of 14 identical ~60,000-MW subunits arranged in two stacked rings (blue and red) of seven subunits each that form two distinct internal polypeptide folding chambers. Homoheptameric (10,000-MW subunits) lids, GroES (yellow), can bind to either end of the barrel and seal the chamber on that side. (b) The GroEL-GroES folding cycle. A partly folded or misfolded polypeptide enters one of the folding chambers (step 1). The second chamber is blocked by a GroES lid. Each ring of seven GroEL subunits binds seven ATPs, hydrolyzes them, and releases the ADPs in a set order coordinated with GroES binding and release and polypeptide binding, folding, and release. The major conformational changes in the

GroEL rings that take place control the binding of the GroES lid that seals the chamber (step 2). The polypeptide remains encased in the chamber capped by the lid, where it can undergo folding until ATP hydrolysis, the slowest, rate-limiting step in the cycle ($t_{1/2} \sim 10$ s) (step 3), induces binding of ATP and a different GroES to the other ring (transient intermediate shown in brackets). This then causes the GroES lid and ADP bound to the peptide-containing ring to be released, opening the chamber and permitting the folded protein to diffuse out of the chamber (step 4). If the polypeptide folded properly, it can proceed to function in the cell. If it remains partially folded or misfolded, it can rebind to an unoccupied GroEL and the cycle can be repeated.

[Part (a) modified from David L. Nelson and Michael M. Cox, *Lehninger: Principles of Biochemistry*, 3d ed., W. H. Freeman and Co.]

mass is captured by hydrophobic residues near the entrance of the GroEL chamber and enters one of the folding chambers (upper chamber in Figure 3-17b). The second chamber is blocked by a GroES lid. Each of the 14 subunits of GroEL can bind ATP, hydrolyze it, and subsequently release ADP. These reactions are concerted for each set of seven subunits in a single ring and lead to major conformational changes. These changes control both the binding of the GroES lid that seals the chamber and the environment of the chamber in which polypeptide folding takes place. The polypeptide remains encased in the chamber capped by the lid. There it can undergo folding until ATP hydrolysis in that chamber, the slowest, rate-limiting step in the cycle ($t_{1/2} \sim 10$ s), induces binding of ATP and a different GroES to the other ring. This then causes the GroES lid and ADP bound to the peptide containing ring to be released, opening the chamber and permitting the folded protein to diffuse out of the chamber. If the polypeptide folded properly, it can proceed to function in the cell. If it remains partially folded or misfolded, it can rebound to an unoccupied GroEL and the cycle can be repeated. There is a reciprocal relationship between the two rings in one GroEL complex. The capping of one chamber by GroES to permit sequestered substrate folding in that chamber is accompanied by the release of substrate polypeptide from the chamber of the second ring (simultaneous binding, folding, and release from the second chamber is not illustrated in Figure 3-17b). There is a striking similarity between the capped-barrel design of GroEL/GroES, in which proteins are sequestered for folding, and the structure of the 26S proteasome that participates in protein degradation (discussed in Section 3.4). In addition, a group of proteins that are part of the AAA⁺ family of ATPases are composed of hexameric rings with a central pore into which substrates can enter for folding or unfolding or in some cases proteolysis; examples of these will be discussed in Chapter 13.

Alternatively Folded Proteins Are Implicated in Diseases

 Recent evidence suggests that a protein may fold into an alternative three-dimensional structure as the result of mutations, inappropriate covalent modifications made after the protein is synthesized, or other as yet unidentified reasons. Such “misfolding” not only leads to a loss of the normal function of the protein but often marks it for proteolytic degradation. However, when degradation isn’t complete or doesn’t keep pace with misfolding, the subsequent accumulation of the misfolded protein or its proteolytic fragments contributes to certain degenerative diseases characterized by the presence of insoluble, disordered aggregates of twisted-together protein, or *plaques*, in various organs, including the liver and brain.

Some neurodegenerative diseases, including Alzheimer’s disease and Parkinson’s disease in humans and transmissible spongiform encephalopathy (“mad cow” disease) in cows and sheep, are marked by the formation of tangled filamentous plaques in a deteriorating brain (Figure 3-18). The *amyloid*

FIGURE 3-18 Alzheimer’s disease is characterized by the formation of insoluble plaques composed of amyloid protein.

(a) At low resolution, an amyloid plaque in the brain of an Alzheimer’s patient appears as a tangle of filaments. (b) The regular structure of filaments from plaques is revealed in the atomic force microscope. Proteolysis of the naturally occurring amyloid precursor protein yields a short fragment, called β -amyloid protein, that for unknown reasons changes from an α -helical to a β -sheet conformation. This alternative structure aggregates into the highly stable filaments (amyloid) found in plaques. Similar pathologic changes in other proteins cause other degenerative diseases. [Courtesy of K. Kosik.]

filaments composing these structures derive from abundant natural proteins such as amyloid precursor protein, which is embedded in the plasma membrane; Tau, a microtubule-binding protein; and prion protein, an “infectious” protein. Influenced by unknown causes, these α helix-containing proteins or their proteolytic fragments fold into alternative β sheet-containing structures that polymerize into very stable filaments. Whether the extracellular deposits of these filaments or the soluble alternatively folded proteins are toxic to the cell is unclear. ■

KEY CONCEPTS of section 3.2

Protein Folding

- The primary structure (amino acid sequence) of a protein determines its three-dimensional structure, which determines its function. In short, function derives from structure; structure derives from sequence.

- Because protein function derives from protein structure, newly synthesized proteins must fold into the correct shape to function properly.
- The planar structure of the peptide bond limits the number of conformations a polypeptide can have (see Figure 3-14).
- The amino acid sequence of a protein dictates its folding into a specific three-dimensional conformation, the native state. Proteins will unfold, or denature, if treated under conditions that disrupt the noncovalent interactions stabilizing their three-dimensional structures.
- Protein folding *in vivo* occurs with assistance from ATP-dependent chaperones. Chaperones can influence proteins in several ways, including preventing misfolding and aggregation, facilitating proper folding, and maintaining an appropriate, stable structure required for subsequent protein activity (see Figure 3-16).
- There are two broad classes of chaperones: (1) molecular chaperones, which bind to a short segment of a protein substrate, and (2) chaperonins, which form folding chambers into which all or part of an unfolded protein can be sequestered, giving it time and an appropriate environment to fold properly.
- Some neurodegenerative diseases are caused by aggregates of proteins that are stably folded in an alternative conformation.

3.3 Protein Binding and Enzyme Catalysis

Proteins perform an extraordinarily diverse array of activities both inside and outside cells, yet most of these diverse functions are based on the ability of proteins to engage in a common activity: binding. Proteins bind to themselves, to other macromolecules, to small molecules, and to ions. In this section, we describe some key features of protein binding and then turn to look at one group of proteins, enzymes, in greater detail. The activities of the other functional classes of proteins (structural, scaffold, transport, regulatory, motor) will be described in later chapters.

Specific Binding of Ligands Underlies the Functions of Most Proteins

The molecule to which a protein binds is called its **ligand**. In some cases, ligand binding causes a change in the shape of a protein. Such conformational changes are integral to the mechanism of action of many proteins and are important in regulating protein activity.

Two properties of a protein characterize how it binds ligands. *Specificity* refers to the ability of a protein to bind one molecule or a very small group of molecules in preference to all other molecules. *Affinity* refers to the tightness or strength of binding, usually expressed as the dissociation constant (K_d). The K_d for a protein-ligand complex, which is the

inverse of the equilibrium constant K_{eq} for the binding reaction, is the most common quantitative measure of affinity (see Chapter 2). The stronger the interaction between a protein and ligand, the lower the value of K_d . Both the specificity and the affinity of a protein for a ligand depend on the structure of the *ligand-binding site*. For high-affinity and highly specific interactions to take place, the shape and chemical properties of the binding site must be complementary to that of the ligand molecule, a property termed **molecular complementarity**. As we saw in Chapter 2, molecular complementarity allows molecules to form multiple noncovalent interactions at close range and thus stick together.

One of the best-studied examples of protein-ligand binding, involving high affinity and exquisite specificity, is that of **antibodies** binding to **antigens**. Antibodies are proteins that circulate in the blood and are made by the immune system (see Chapter 23) in response to antigens, which are usually macromolecules present in infectious agents (e.g., a bacterium or a virus) or other foreign substances (e.g., proteins or polysaccharides in pollens). Different antibodies are generated in response to different antigens, and these antibodies have the remarkable characteristic of binding specifically to (“recognizing”) a part of the antigen, called an **epitope**, which initially induced the production of the antibody, and not to other molecules. Antibodies act as specific sensors for antigens, forming antibody-antigen complexes that initiate a cascade of protective reactions in cells of the immune system.

All antibodies are Y-shaped molecules formed from two identical longer, or *heavy*, chains and two identical shorter, or *light*, chains (Figure 3-19a). Each arm of an antibody molecule contains a single light chain linked to a heavy chain by a disulfide bond. Near the end of each arm are six highly variable loops, called *complementarity-determining regions* (CDRs), which form the antigen-binding sites. The sequences of the six loops are highly variable among antibodies, generating unique complementary ligand-binding sites that make them specific for different epitopes (Figure 3-19b). The intimate contact between these two surfaces, stabilized by numerous noncovalent interactions, is responsible for the extremely precise binding specificity exhibited by an antibody.

The specificity of antibodies is so precise that they can distinguish between the cells of individual members of a species and in some cases between proteins that differ by only a single amino acid, or even between proteins with identical sequences and only different post-translational modifications. Because of their specificity and the ease with which they can be produced (see Chapter 23), antibodies are highly useful reagents used in many of the experiments discussed in subsequent chapters.

We will see many examples of protein-ligand binding throughout this book, including hormones binding to receptors (see Chapter 15), regulatory molecules binding to DNA (see Chapter 7), and cell-adhesion molecules binding to extracellular matrix (see Chapter 20), to name just a few. Here we focus on how the binding of one class of proteins, enzymes,

FIGURE 3-19 Protein-ligand binding of antibodies. (a) Ribbon model of an antibody. Every antibody molecule of the immunoglobulin IgG class consists of two identical heavy chains (light and dark red) and two identical light chains (blue) covalently linked by disulfide bonds. The inset shows a diagram of the overall structure containing the two heavy and two light chains. (b) The hand-in-glove fit between an antibody and the site to which it binds (epitope) on its target antigen—in this case, chicken egg-white lysozyme. Regions where the two molecules make contact are shown as surfaces. The antibody contacts the antigen with residues from all its complementarity-determining regions (CDRs). In this view, the molecular complementarity of the antigen and antibody is especially apparent where “fingers” extending from the antigen surface are opposed to “clefts” in the antibody surface.

to their ligands results in the catalysis of the chemical reactions essential for the survival and function of cells.

Enzymes Are Highly Efficient and Specific Catalysts

The subset of proteins that catalyze chemical reactions, the making and breaking of covalent bonds, is called **enzymes**, and enzymes’ ligands are called **substrates**. Enzymes make up a large and very important class of proteins—indeed, almost every chemical reaction in the cell is catalyzed by a

specific catalyst, usually an enzyme. Another form of catalytic macromolecule in cells is made from RNA. These RNAs are called **ribozymes** (see Chapter 4).

Thousands of different types of enzymes, each of which catalyzes a single chemical reaction or set of closely related reactions, have been identified. Certain enzymes are found in the majority of cells because they catalyze the synthesis of common cellular products (e.g., proteins, nucleic acids, and phospholipids) or take part in harvesting energy from nutrients (e.g., by the conversion of glucose and oxygen into carbon dioxide and water during cellular respiration). Other enzymes are present only in a particular type of cell because they catalyze chemical reactions unique to that cell type (e.g., the enzymes in nerve cells that convert tyrosine into dopamine, a neurotransmitter). Although most enzymes are located within cells, some are secreted and function at extracellular sites such as the blood, the digestive tract, or even outside the organism (e.g., toxic enzymes in the venom of poisonous snakes).

Like all **catalysts** (see Chapter 2), enzymes increase the rate of a reaction but do not affect the extent of a reaction, which is determined by the change in free energy ΔG between reactants and products and are not themselves permanently changed as a consequence of the reaction they catalyze. Enzymes increase the reaction rate by lowering the energy of the transition state and therefore the activation energy required to reach it (Figure 3-20). In the test tube, catalysts such as charcoal and platinum facilitate reactions but usually only at high temperatures or pressures, at extremes of high or low pH, or in organic solvents. Within cells, however, enzymes

FIGURE 3-20 Effect of an enzyme on the activation energy of a chemical reaction. This hypothetical reaction pathway depicts the changes in free energy, G , as a reaction proceeds. A reaction will take place spontaneously only if the total G of the products is less than that of the reactants (negative ΔG). However, all chemical reactions proceed through one or more high-energy transition states, and the rate of a reaction is inversely proportional to the activation energy ($\Delta G^\ddagger$), which is the difference in free energy between the reactants and the transition state (highest point along the pathway). Enzymes and other catalysts accelerate the rate of a reaction by reducing the free energy of the transition state and thus $\Delta G^\ddagger$.

must function effectively in an aqueous environment at 37 °C and 1 atmosphere pressure and at physiologic pH values, usually 6.5–7.5 but sometimes lower. Remarkably, enzymes exhibit immense catalytic power, accelerating the rates of reactions 10^6 – 10^{12} times that of the corresponding uncatalyzed reactions under otherwise similar conditions.

An Enzyme's Active Site Binds Substrates and Carries Out Catalysis

Certain amino acids of an enzyme are particularly important in determining its specificity and catalytic power. In the native conformation of an enzyme, critically important amino acids (which usually come from different parts of the linear sequence of the polypeptide) are brought into proximity, forming a cleft in the surface called the **active site** (Figure 3-21). An active site usually makes up only a small part of the total protein, with the remaining part involved in folding of the polypeptide, regulation of the active site, and interactions with other molecules.

An active site consists of two functionally important regions: the **substrate-binding site**, which recognizes and binds the substrate or substrates, and the **catalytic site**, which carries out the chemical reaction once the substrate has bound. The catalytic groups in the catalytic site are amino acid side chains and backbone carbonyl and amino groups. In some enzymes, the catalytic and substrate-binding sites overlap; in others, the two regions are structurally distinct.

The substrate-binding site is responsible for the remarkable specificity of enzymes—their ability to act selectively on one substrate or a small number of chemically similar substrates. The alteration of the structure of an enzyme's substrate by only one or a few atoms, or a subtle change in the geometry (e.g., stereochemistry) of the substrate, can result in a variant molecule that is no longer a substrate of the enzyme. As with the specificity of antibodies for antigens described above, the specificity of enzymes for substrates is a consequence of

FIGURE 3-21 Active site of the enzyme trypsin. (a) An enzyme's active site is composed of a binding pocket, which binds specifically to a substrate, and a catalytic site, which carries out catalysis. (b) A surface representation of the serine protease trypsin. Active site clefts containing the catalytic site (side chains of the catalytic triad Ser-195, Asp-102, and His-57 shown as stick figures) and the substrate side chain specificity binding pocket are clearly visible. [Part (b) courtesy of P. Teesdale-Spittle.]

the precise molecular complementarity between its substrate-binding site and the substrate. Usually only one or a few substrates can fit precisely into a binding site.

The idea that substrates might bind to enzymes in the manner of a key fitting into a lock was suggested first by Emil Fischer in 1894. In 1913 Leonor Michaelis and Maud Leonora Menten provided crucial evidence supporting this hypothesis. They showed that the rate of an enzymatic reaction was proportional to the substrate concentration at low substrate concentrations, but that as the substrate concentrations increased, the rate reached a **maximal velocity**, $V_{\max}$, and became substrate concentration independent, with the value of $V_{\max}$ being directly proportional to the amount of enzyme present in the reaction mixture (Figure 3-22).

FIGURE 3-22 K_m and $V_{\max}$ for an enzyme-catalyzed reaction.

K_m and $V_{\max}$ are determined from analysis of the dependence of the initial reaction velocity on substrate concentration. The shape of these hypothetical kinetic curves is characteristic of a simple enzyme-catalyzed reaction in which one substrate (S) is converted into product (P). The initial velocity is measured immediately after addition of enzyme to substrate before the substrate concentration changes appreciably. (a) Plots of the initial velocity at two different concentrations of enzyme [E] as a function of substrate concentration [S]. The [S] that yields a half-maximal reaction rate is the Michaelis constant K_m , a measure of the affinity of E for turning S into P. Quadrupling the enzyme concentration causes a proportional increase in the reaction rate, and so the maximal velocity $V_{\max}$ is quadrupled; the K_m , however, is unaltered. (b) Plots of the initial velocity versus substrate concentration with a substrate S for which the enzyme has a high affinity and with a substrate S' for which the enzyme has a lower affinity. Note that the $V_{\max}$ is the same with both substrates because [E] is the same but that K_m is higher for S', the low-affinity substrate.

FIGURE 3-23 Schematic model of an enzyme's reaction mechanism. Enzyme kinetics suggest that enzymes (E) bind substrate molecules (S) through a fixed and limited number of sites on the enzymes (the active sites). The bound species is known as an enzyme-substrate (ES) complex. The ES complex is in equilibrium with the unbound enzyme and substrate and is an intermediate step in the conversion of substrate to products (P).

They deduced that this saturation at high substrate concentrations was due to the binding of substrate molecules (S) to a fixed and limited number of sites on the enzymes (E), and they called the bound species the enzyme-substrate (ES) complex. They proposed that the ES complex is in equilibrium with the unbound enzyme and substrate and is an intermediate step in the ultimately irreversible conversion of substrate to product (P) (Figure 3-23):

and that the rate V_0 of formation of product at a particular substrate concentration $[S]$ is given by what is now called the *Michaelis-Menten equation*:

$$V_0 = V_{\max} \frac{[S]}{[S] + K_m} \quad (3-1)$$

where the **Michaelis constant**, K_m , a measure of the affinity of an enzyme for its substrate, is the substrate concentration that yields a half-maximal reaction rate (i.e., $1/2 V_{\max}$ in Figure 3-22). The K_m is somewhat similar in nature, but not identical, to the dissociation constant, K_d (see Chapter 2). The smaller the value of K_m , the more effective the enzyme is at making product from dilute solutions of substrate and the lower the substrate concentration needed to reach half-maximal velocity. The smaller the K_d , the lower the ligand concentration needed to reach 50 percent of binding. The concentrations of the various small molecules in a cell vary widely, as do the K_m values for the different enzymes that act on them. A good rule of thumb is that the intracellular concentration of a substrate is approximately the same as, or somewhat greater than, the K_m value of the enzyme to which it binds.

The rates of reaction at substrate saturation vary enormously among enzymes. The maximum number of substrate molecules converted to product at a single enzyme active site per second is called the *turnover number*, which can be less than 1 for very slow enzymes. The turnover number for carbonic anhydrase, one of the fastest enzymes, is 6×10^5 molecules/s.

Many enzymes catalyze the conversion of substrates to products by dividing the process into multiple, discrete chemical reactions that involve multiple, distinct enzyme substrate complexes (ES, ES', ES'', etc.) generated prior to the final release of the products:

The energy profiles for such multistep reactions involve multiple hills and valleys (Figure 3-24), and methods have been developed to trap the intermediates in such reactions to learn more about the details of how enzymes catalyze reactions.

Serine Proteases Demonstrate How an Enzyme's Active Site Works

Serine proteases, a large family of protein-cleaving, or proteolytic, enzymes, are used throughout the biological world—to digest meals (the pancreatic enzymes trypsin, chymotrypsin, and elastase), to control blood clotting (the enzyme thrombin), even to help silk moths chew their way out of their cocoons (cocoanase). This class of enzymes usefully illustrates how an enzyme's substrate-binding site and catalytic site cooperate in multistep reactions to convert substrates to products. Here we will consider how trypsin and its two evolutionarily closely related pancreatic proteases, chymotrypsin and elastase, catalyze cleavage of a peptide bond:

where in the polypeptide substrate P_1 is the part of the protein on the N-terminal side of the peptide bond and P_2 is the

FIGURE 3-24 Free-energy reaction profiles of uncatalyzed and multistep enzyme-catalyzed reactions. (a) The free-energy reaction profile of a hypothetical simple uncatalyzed reaction converting substrate (S) to product (P) via a single high-energy transition state. (b) Many enzymes catalyze such reactions by dividing the process into

multiple discrete steps, in this case the initial formation of an ES complex followed by conversion via a single transition state (EX^*) to the free enzyme (E) and P. The activation energy for each of these steps is significantly less than the activation energy for the uncatalyzed reaction; thus the enzyme dramatically enhances the reaction rate.

portion on the C-terminal side. We first consider how serine proteases bind specifically to their substrates and then show in detail how catalysis takes place.

Figure 3-25a shows how a substrate polypeptide binds to the substrate-binding site in the active site of trypsin. There

are two key binding interactions. First, the substrate (black polypeptide backbone) and enzyme (blue polypeptide backbone) form hydrogen bonds that resemble a β sheet. Second, a key side chain of the substrate that determines which peptide in the substrate is to be cleaved extends into the enzyme's *side-chain-specificity binding pocket*, at the bottom of which resides the negatively charged side chain of the enzyme's Asp-189. Trypsin has a marked preference for hydrolyzing substrates at the carboxyl ($C=O$) side of an amino acid with a long positively charged side chain (arginine or lysine) because the side chain is stabilized in the enzyme's specificity binding pocket by the negative Asp-189.

Slight differences in the structures of otherwise similar specificity pockets help explain the differing substrate specificities of two related serine proteases: chymotrypsin prefers large aromatic groups (as in Phe, Tyr, Trp), and elastase prefers the small side chains of Gly and Ala (Figure 3-25b). The uncharged Ser-189 in chymotrypsin allows large, uncharged, hydrophobic side chains to bind stably in the pocket. The

FIGURE 3-25 Substrate binding in the active site of trypsin-like serine proteases. (a) The active site of trypsin (purple and blue molecule) with a bound substrate (black molecule). The substrate forms a two-stranded β sheet with the binding site, and the side chain of an arginine (R_3) in the substrate is bound in the side-chain-specificity binding pocket. Its positively charged guanidinium group is stabilized by the negative charge on the side chain of the enzyme's Asp-189. This binding aligns the peptide bond of the arginine appropriately for hydrolysis catalyzed by the enzyme's active-site catalytic triad (side chains of Ser-195, His-57, and Asp-102). (b) The amino acids lining the side-chain-specificity binding pocket determine its shape and charge and thus its binding properties. Trypsin accommodates the positively charged side chains of arginine and lysine; chymotrypsin, large, hydrophobic side chains such as phenylalanine; and elastase, small side chains such as glycine and alanine. [Part (a) modified from J. J. Perona and C. S. Craik, 1997, *J. Biol. Chem.* 272(48):29987–29990.]

specificity of elastase is influenced by the replacement of glycines in the sides of the pocket in trypsin with the branched aliphatic side chains of valines (Val-216 and Val-190) that obstruct the pocket (Figure 3-25b). As a consequence, large side chains in substrates are prevented from fitting into the pocket of elastase, whereas substrates with the short alanine or glycine side chains at this position can bind well and be subject to subsequent cleavage.

In the catalytic site, all three enzymes use the hydroxyl group on the side chain of a serine in position 195 to catalyze the hydrolysis of peptide bonds in protein substrates. A catalytic triad formed by the three side chains of Ser-195, His-57, and Asp-102 participates in what is essentially a two-step hydrolysis reaction. Figure 3-26 shows how the catalytic triad cooperates in breaking the peptide bond, with Asp-102 and His-57 supporting the attack of the hydroxyl oxygen of Ser-195

on the carbonyl carbon in the substrate. This attack initially forms an unstable transition state with four groups attached to this carbon (tetrahedral intermediate). Breaking of the C—N peptide bond then releases one part of the substrate protein ($\text{NH}_3\text{—P}_2$), while the other part remains covalently attached to the enzyme via an ester bond to the serine's oxygen, forming a relatively stable acyl enzyme intermediate. The subsequent replacement of this oxygen by one from water, in a reaction involving another unstable tetrahedral intermediate, leads to release of the final product ($\text{P}_1\text{—COOH}$). The tetrahedral intermediate transition states are partially stabilized by hydrogen bonding from the enzyme's backbone amino groups in what is called the *oxyanion hole*. The large family of serine proteases and related enzymes with an active site serine illustrates how an efficient reaction mechanism is used over and over by distinct enzymes to catalyze similar reactions.

FIGURE 3-26 Mechanism of serine-protease-mediated hydrolysis of peptide bonds. The catalytic triad of Ser-195, His-57, and Asp-102 in the active sites of serine proteases employs a multistep mechanism to hydrolyze peptide bonds in target proteins. (a) After a polypeptide substrate binds to the active site (see Figure 3-25), forming an ES complex, the hydroxyl oxygen of Ser-195 attacks the carbonyl carbon of the substrate's targeted peptide bond (yellow). Movements of electrons are indicated by arrows. (b) This attack results in the formation of a transition state called the *tetrahedral intermediate*, in which the negative charge on the substrate's oxygen is stabilized by hydrogen bonds formed with the enzyme's *oxyanion hole*. (c) Additional electron movements result in the breaking of the peptide bond,

release of one of the reaction products ($\text{NH}_2\text{—P}_2$), and formation of the acyl enzyme (ES' complex). (d) An oxygen from a solvent water molecule then attacks the carbonyl carbon of the acyl enzyme. (e) This attack results in the formation of a second tetrahedral intermediate. (f) Additional electron movements result in the breaking of the Ser-195-substrate bond (formation of the EP complex) and release of the final reaction product ($\text{P}_1\text{—COOH}$). The side chain of His-57, which is held in the proper orientation by hydrogen bonding to the side chain of Asp-102, facilitates catalysis by withdrawing and donating protons throughout the reaction (*inset*). If the pH is too low and the side chain of His-57 is protonated, it cannot participate in catalysis and the enzyme is inactive.

FIGURE 3-27 pH dependence of enzyme activity. Ionizable (pH-titratable) groups in the active sites or elsewhere in enzymes often must be either protonated or deprotonated to permit proper substrate binding or catalysis or to permit the enzyme to adopt the correct conformation. Measurement of enzyme activity as a function of pH can be used to identify the pK_a 's of these groups. The pancreatic serine proteases, such as chymotrypsin (right curve), exhibit maximum activity around pH 8 because of titration of the active site His-57 (required for catalysis, $pK_a \sim 6.8$) and of the amino terminus of the protein (required for proper conformation, $pK_a \sim 9$). Many lysosomal hydrolases have evolved to exhibit a lower pH optimum (~ 4.5 , left curve) to match the low internal pH in lysosomes in which they function. [Adapted from P. Lozano, T. De Diego, and J. L. Iborra, 1997, *Eur. J. Biochem.* **248**(1):80–85, and W. A. Judice et al., 2004, *Eur. J. Biochem.* **271**(5):1046–1053.]

The serine protease mechanism points out several general key features of enzymatic catalysis: (1) enzyme catalytic sites have evolved to stabilize the binding of a transition state, thus lowering the activation energy and accelerating the overall reaction; (2) multiple side chains, together with the polypeptide backbone, carefully organized in three dimensions, work together to chemically transform substrate into product, often by multistep reactions; and (3) acid-base catalysis mediated by one or more amino acid side chains is often used by enzymes, as when the imidazole group of His-57 in serine proteases acts as a base to remove the hydrogen from Ser-195's hydroxyl group. As a consequence, often only a particular ionization state (protonated or nonprotonated) of one or more amino acid side chains in the catalytic site is compatible with catalysis, and thus the enzyme's activity is pH dependent.

For example, the imidazole of His-57 in serine proteases, whose pK_a is ~ 6.8 , can help the Ser-195 hydroxyl attack the substrate only if it is not protonated. Thus the activity of the protease is low at $pH < 6.8$, and the shape of the pH activity profile in the pH range 4–8 matches the titration of the His-57 side chain, which is governed by the Henderson-Hasselbalch equation, with an inflection near pH 6.8 (see chymotrypsin data in Figure 3-27 and see Chapter 2). The activity drops at higher pH values, generating a bell-shaped curve, because the proper folding of the protein is disrupted when the amino group at the protein's amino terminus ($pK_a \sim 9$) is deprotonated; the conformation near the active site changes as a consequence.

The pH sensitivity of an enzyme's activity can be due to changes in the ionization of catalytic groups, groups that participate directly in substrate binding, or groups that influence the conformation of the protein. Pancreatic proteases evolved to function in the neutral or slightly basic conditions in the intestines; hence their pH optima are ~ 8 . Proteases and other hydrolytic enzymes that function in acidic conditions must employ a different catalytic mechanism. This is the case for enzymes within the stomach ($pH \sim 1$) such as the protease pepsin or those within lysosomes ($pH \sim 4.5$), which play a key role in degrading macromolecules within cells (see lysosomal enzyme data in Figure 3-27). Indeed, lysosomal hydrolases, which degrade a wide variety of biomolecules (proteins, lipids, etc.), are relatively inactive at the pH in the cytosol (~ 7), helping protect a cell from self-digestion if these enzymes escape the confines of the membrane-bound lysosome.

One key feature of enzymatic catalysis not seen in serine proteases but found in many other enzymes is a *cofactor* or *prosthetic group*. This “helper” group is a nonpolypeptide small molecule or ion (e.g., iron, zinc, copper, manganese) that is bound in the active site and plays an essential role in the reaction mechanism. Small organic prosthetic groups in enzymes are also called *coenzymes*. Some of these are chemically modified during the reaction and thus need to be replaced or regenerated after each reaction; others are not. Examples include NAD^+ (nicotinamide adenine dinucleotide), FAD (flavin adenine dinucleotide) (see Figure 2-33), and heme groups that bind oxygen in hemoglobin or transfer electrons in some cytochromes (see Figure 12-14). Thus the chemistry catalyzed by enzymes is not restricted by the limited number of types of amino acids in polypeptide chains. Many vitamins—for example, the B vitamins, thiamine (B_1), riboflavin (B_2), niacin (B_3), and pyridoxine (B_6), and vitamin C—which cannot be synthesized in mammalian cells, function as or are used to generate coenzymes. That is why supplements of vitamins must be added to the liquid medium in which mammalian cells are grown in the laboratory (see Chapter 9).

Small molecules that can bind to active sites and disrupt catalytic reactions are called *enzyme inhibitors*. Such inhibitors are useful tools for studying the roles of enzymes in cells and whole organisms. Inhibitors that directly bind to an enzyme's binding site and thus compete directly with the normal substrates' ability to bind substrate are called competitive inhibitors. Alternatively, inhibitors can interfere with enzyme activity in other ways, for example by binding to some other site on the enzyme and changing its conformation; this is called noncompetitive inhibition. Inhibitors complement the use of mutations in genes and a technique called RNA interference (RNAi) for probing an enzyme's function in cells (see Chapter 5). In all three approaches the cellular consequences of disrupting an enzyme's activity can be used to deduce the normal function of the enzyme. The same approaches can be used to study the functions of non-enzymatic macromolecules. However, interpreting results of inhibitor studies can be complicated if, as is often the case, the inhibitors block the activity of more than one protein.

 Small-molecule inhibition of protein activity is the basis for most drugs and also for chemical warfare agents. Aspirin inhibits enzymes called cyclooxygenases, whose products can cause pain. Sarin and other nerve gases react with the active serine hydroxyl groups of both serine proteases and a related enzyme, acetylcholine esterase, which is a key enzyme in regulating nerve conduction (see Chapter 22). ■

Enzymes in a Common Pathway Are Often Physically Associated with One Another

Enzymes taking part in a common metabolic process (e.g., the degradation of glucose to pyruvate during glycolysis; see Chapter 12) are generally located in the same cellular compartment, be it the cytosol, at a membrane, or within a particular organelle. Within this compartment, products from one reaction can move by diffusion to the next enzyme in the pathway. However, diffusion entails random movement and can be a slow, relatively inefficient process for moving molecules between enzymes (Figure 3-28a). To overcome this impediment, cells have evolved mechanisms for bringing enzymes in a common pathway into close proximity, a process called metabolic coupling.

FIGURE 3-28 Assembly of enzymes into efficient multienzyme complexes. In the hypothetical reaction pathways illustrated here, the initial reactants are converted into final products by the sequential action of three enzymes: A, B, and C. (a) When the enzymes are free in solution or even constrained within the same cellular compartment, the intermediates in the reaction sequence must diffuse from one enzyme to the next, an inherently slow process. (b) Diffusion is greatly reduced or eliminated when the individual enzymes associate into multisubunit complexes, either by themselves or with the aid of a scaffold protein. (c) The closest integration of different catalytic activities occurs when the enzymes are fused at the genetic level, becoming domains in a single polypeptide chain.

In the simplest such mechanism, polypeptides with different catalytic activities cluster closely together as subunits of a multimeric enzyme or assemble on a common “scaffold” that holds them together (Figure 3-28b). This arrangement allows the products of one reaction to be channeled directly to the next enzyme in the pathway. In some cases, independent proteins have been fused together at the genetic level to create a single multidomain, multifunctional enzyme (Figure 3-28c). Metabolic coupling usually involves large multiprotein complexes, as described earlier in this chapter.

KEY CONCEPTS of Section 3.3

Protein Binding and Enzyme Catalysis

- A protein’s function depends on its ability to bind other molecules known as ligands. For example, antibodies bind to a group of ligands known as antigens and enzymes bind to reactants called substrates that will be converted by chemical reactions into products.
- The specificity of a protein for a particular ligand refers to the preferential binding of one or a few closely related ligands. The affinity of a protein for a particular ligand refers to the strength of binding, usually expressed as the dissociation constant K_d .
- Proteins are able to bind to ligands because of molecular complementarity between the ligand-binding sites and the corresponding ligands.
- Enzymes are catalytic proteins that accelerate the rate of cellular reactions by lowering the activation energy and stabilizing transition-state intermediates (see Figure 3-20).
- An enzyme’s active site, which is usually only a small part of the protein, comprises two functional parts: a substrate-binding site and a catalytic site. The substrate-binding site is responsible for the exquisite specificity of enzymes owing to its molecular complementarity with the substrate and the transition state.
- The initial binding of substrates (S) to enzymes (E) results in the formation of an enzyme-substrate complex (ES), which then undergoes one or more reactions catalyzed by the catalytic groups in the active site until the products (P) are formed.
- From plots of reaction rate versus substrate concentration, two characteristic parameters of an enzyme can be determined: the Michaelis constant, K_m , a rough measure of the enzyme’s affinity for converting substrate into product, and the maximal velocity, V_{max} , a measure of its catalytic power (see Figure 3-22).
- The rates of enzyme-catalyzed reactions vary enormously, with the turnover numbers (number of substrate molecules converted to products at a single active site at substrate saturation) ranging between <1 to 6×10^5 molecules/s.

- Many enzymes catalyze the conversion of substrates to products by dividing the process into multiple discrete chemical reactions that involve multiple distinct enzyme substrate complexes (ES', ES'' etc.).
- Serine proteases hydrolyze peptide bonds in protein substrates using as catalytic groups the side chains of Ser-195, His-57, and Asp-102. Amino acids lining the specificity binding pocket in the binding site of serine proteases determine the residue in a protein substrate whose peptide bond will be hydrolyzed and account for differences in the specificity of trypsin, chymotrypsin, and elastase.
- Enzymes often use acid-base catalysis mediated by one or more amino acid side chains, such as the imidazole group of His-57 in serine proteases, to catalyze reactions. The pH dependence of protonation of catalytic groups (pK_a) is often reflected in the pH-rate profile of the enzyme's activity.
- In some enzymes, nonpolypeptide small molecules or ions, called *cofactors* or *prosthetic groups*, can bind to the active site and play an essential role in enzymatic catalysis. Small organic prosthetic groups in enzymes are also called *coenzymes*; vitamins, which cannot be synthesized in higher animal cells, function as or are used to generate coenzymes.
- Enzymes in a common pathway are located within specific cell compartments and may be further associated as domains of a monomeric protein, subunits of a multimeric protein, or components of a protein complex assembled on a common scaffold (see Figure 3-28).

3.4 Regulating Protein Function

Most processes in cells do not take place independently of one another or at a constant rate. The activities of all proteins and other biomolecules are regulated to integrate their functions for optimal performance for survival. For example, the catalytic activity of enzymes is regulated so that the amount of reaction product is just sufficient to meet the needs of the cell. As a result, the steady-state concentrations of substrates and products will vary depending on cellular conditions. Regulation of nonenzymatic proteins—the opening or closing of membrane channels or the assembly of a macromolecular complex, for example—is also essential.

In general, there are three ways to regulate protein activity. First, cells can increase or decrease the steady-state level of the protein by altering its rate of synthesis, its rate of degradation, or both. Second, cells can change the intrinsic activity, as distinct from the amount, of the protein. For example, through noncovalent and covalent interactions, cells can change the affinity of substrate binding, or the fraction of time the protein is in an active versus inactive conformation. Third, there can be a change in location or concentration within the cell of the protein itself, the target of the protein's activity (e.g., an enzyme's substrate), or some other molecule required for the protein's activity (e.g., an enzyme's cofactor).

All three types of regulation play essential roles in the lives and functions of cells. In this section, we first discuss mechanisms for regulating the amount of a protein and then turn to noncovalent and covalent interactions that regulate protein activity.

Regulated Synthesis and Degradation of Proteins Is a Fundamental Property of Cells

The rate of synthesis of proteins is determined by the rate at which the DNA encoding the protein is converted to mRNA (transcription), the steady-state amount of the active mRNA in the cell, and the rate at which the mRNA is converted into newly synthesized protein (translation). These important pathways are described in detail in Chapter 4.

The life span of intracellular proteins varies from as short as a few minutes for mitotic cyclins, which help regulate passage through the mitotic stage of cell division (see Chapter 19), to as long as the age of an organism for proteins in the lens of the eye. Protein life span is controlled primarily by regulated protein degradation.

There are two especially important roles for protein degradation. First, degradation removes proteins that are potentially toxic, improperly folded or assembled, or damaged—including the products of mutated genes and proteins damaged by chemically active cell metabolites or stress (e.g., heat shock). Despite the existence of chaperone-mediated protein folding, some of the newly made proteins are rapidly degraded because they are misfolded. This might occur due to failure of timely engagement of the necessary chaperones to guide their folding or their defective assembly into complexes. Most other proteins are degraded more slowly, about 1–2 percent degradation per hour in mammalian cells. Second, the controlled destruction of otherwise normal proteins provides a powerful mechanism for maintaining the appropriate levels of the proteins and their activities and for permitting rapid changes in these levels to help the cells respond to changing conditions.

Eukaryotic cells have several pathways for degrading proteins. One major pathway is degradation by enzymes within lysosomes, membrane-limited organelles whose acidic interior (pH ~4.5) is filled with a host of hydrolytic enzymes. Lysosomal degradation is directed primarily toward aged or defective organelles of the cell—a process called autophagy (see Chapter 14)—and toward extracellular proteins taken up by the cell. Lysosomes will be discussed at length in later chapters. Here we will focus on another important pathway: cytoplasmic protein degradation by proteasomes, which can account for up to 90 percent of the protein degradation in mammalian cells.

The Proteasome Is a Molecular Machine Used to Degrade Proteins

Proteasomes are very large, protein-degrading macromolecular machines that influence many different cellular functions, including the cell cycle (see Chapter 19), transcription,

FIGURE 3-29 Ubiquitin- and proteasome-mediated proteolysis. (a) *Left:* The 26S proteasome has a cylindrical structure with a 19S cap (blue) at each end of a 20S core consisting of four stacked heptameric rings (~110 Å diameter × 160 Å long) each containing either α (outer rings) or β (inner rings) subunits (yellow). *Right:* Cutaway view of 20S core showing inner chambers. Proteolysis of ubiquitin-tagged proteins occurs within the inner chamber of the core formed by the β rings. (b) Proteins are targeted for proteasomal degradation by polyubiquitination. Enzyme E1 is activated by attachment of a ubiquitin (Ub) molecule (step 1) and then transfers this Ub molecule to a cysteine residue in E2 (step 2). Ubiquitin ligase (E3) transfers the bound Ub molecule on E2 to the side-chain —NH₂ of a lysine residue in a target protein, forming an isopeptide bond (step 3). Additional Ub molecules are added to the Ub-modified target protein via isopeptide bonds to the previously added Ub by repeating steps 3–5, forming a polyubiquitin chain (step 4). The polyubiquitylated target is recognized by the proteasome cap, which uses deubiquitinase enzymes to remove the Ub groups and ATP hydrolysis to drive unfolding and transfer of the unfolded protein into the proteolysis chamber in the core, from which the short peptide digestion fragments are later released (step 5) [Part (a) from W. Baumeister et al., 1998, *Cell* 92:357, courtesy of W. Baumeister and modified from M. Bochtler et al., 1999, *Ann. Rev. Biophys. Biomol. Struct.* 28:295–317.]

DNA repair (see Chapter 4), programmed cell death or apoptosis (see Chapter 21), recognition and response to infection by foreign organisms (see Chapter 23), and removal of misfolded proteins. There are approximately 30,000 proteasomes in a typical mammalian cell.

Proteasomes consist of ~50 protein subunits and have a mass of $2\text{--}2.4 \times 10^6$ Da. Proteasomes have a cylindrical, barrel-like catalytic core called the 20S proteasome (where S is a Svedberg unit based on the sedimentation properties of the particle and is proportional to its size), which is approximately 14.8 nm tall and 11.3 nm in diameter. Bound to the ends of this core are either one or two 19S cap complexes (Figure 3-29a) that regulate the activity of the 20S catalytic core. When the core and one or two caps are combined, they are both referred to as the 26S complex, even though the two-cap-containing complex is larger (30S). A 19S cap has 16–18 protein subunits, six of which can hydrolyze ATP (i.e., they are AAA-type ATPases) to provide the energy needed to unfold protein substrates and selectively transfer

them into the inner chamber of the proteasome's catalytic core. Genetic studies in yeast have shown that cells cannot survive without functional proteasomes, thus demonstrating their importance. Furthermore, proper proteasomal activity is so important that cells will expend as much as 30 percent of the energy needed to synthesize a protein to degrade it in a proteasome.

The 20S proteasomal catalytic core comprises two inner rings of seven β subunits each, with three proteolytic active sites per ring facing toward the inner chamber of the ~1.7-nm-diameter barrel and two outer rings of seven α subunits each that control substrate access (Figure 3-29a). Proteasomes can degrade most proteins thoroughly because the three active sites in each β subunit ring can cleave after hydrophobic residues, acidic residues, or basic residues. Polypeptide substrates must enter the chamber via a regulated ~1.3-nm-diameter aperture at the center of the outer α subunit rings. In the 26S proteasome, the opening of the aperture, which is narrow and often allows the entry of only

unfolded proteins, is controlled by ATPases in the 19S cap that also participate in selectively binding and unfolding the substrate (Figure 3-29b, *bottom right*). The short peptide products of proteasomal digestion (2–24 residues long) exit the chamber and are further degraded rapidly by cytosolic peptidases, eventually being converted to individual (“free”) amino acids. One researcher has quipped that a proteasome is a “cellular chamber of doom” in which proteins suffer a “death by a thousand cuts.”

 Inhibitors of proteasome function can be used therapeutically. Because of the global importance of proteasomes for cells, continuous, complete inhibition of proteasomes kills cells. However, partial proteasome inhibition for short intervals has been introduced as an approach to cancer chemotherapy. To survive and grow, cells normally require the robust activity of a regulatory protein called *NF κ B* (see Chapter 16) as well as other, similar “pro-survival” proteins. In turn, *NF κ B* can function fully and promote survival only when its inhibitor, *I κ B*, is disengaged and degraded by proteasomes (see Chapter 16). Partial inhibition of proteasomal activity by a small-molecule inhibitor drug results in increased levels of *I κ B* and, consequently, reduced *NF κ B* activity (that is, loss of pro-survival activity). Cells subsequently die by apoptosis. Because at least some types of tumor cells are more sensitive to being killed by proteasome inhibitors than normal cells are, *controlled* administration of proteasome inhibitors, at levels that kill the cancer cells but not normal cells, has proven to be an effective therapy for at least one type of lethal cancer, multiple myeloma. ■

Ubiquitin Marks Cytosolic Proteins for Degradation in Proteasomes

If proteasomes are to rapidly degrade only those proteins that are either defective or scheduled to be removed, they must be able to distinguish between those proteins that need to be degraded and those that don't. Cells mark proteins that should be degraded by covalently attaching to them a linear chain of multiple copies of a 76-residue polypeptide called **ubiquitin** that is highly conserved from yeast to humans. This “polyubiquitin tail” serves as a cellular “kiss of death,” marking the protein for destruction in the proteasome. The ubiquitination process (Figure 3-29b) involves three distinct steps:

1. Activation of *ubiquitin-activating enzyme* (*E1*) by the addition of a ubiquitin molecule, a reaction that requires ATP;
2. Transfer of this ubiquitin molecule to a cysteine residue in *ubiquitin-conjugating enzyme* (*E2*);
3. Formation of a covalent bond between the carboxyl group of the C-terminal glycine 76 of the ubiquitin bound to *E2* and the amino group of the side chain of a lysine residue in the target protein, a reaction catalyzed by *ubiquitin-protein ligase* (*E3*). This type of bond is called an *isopeptide bond* because it covalently links a side chain amino group, rather than the α amino group, to the carboxyl group.

Subsequent ligase reactions covalently attach the C-terminal glycine of an additional ubiquitin via an isopeptide bond to the side chain of lysine 48 of the previously added ubiquitin to generate a polyubiquitin chain covalently attached to the target protein.

Following attachment of four or more ubiquitins in the polyubiquitin chain, the 19S regulatory cap of the 26S proteasome (sometimes with the help of accessory proteins) recognizes the polyubiquitin-labeled proteins and unfolds and transports them into the proteasome for degradation (see Figure 3-29b). As a polyubiquitinated substrate is unfolded and passed into the core of the proteasome, enzymes called deubiquitinases (*Dubs*) hydrolyze the bonds between individual ubiquitins and between the targeted protein and ubiquitin, recycling the ubiquitins for additional rounds of protein modification (see Figure 3-29b). Analysis of the human genome sequence indicates the presence of ~90 *Dubs*, about 80 percent of which use cysteine in a catalytic triad, similar to serine proteases described earlier. In some *Dubs*, zinc is a key participant in the catalytic reactions.

Specificity of Degradation Targeting of specific proteins for proteasomal degradation is primarily achieved through the substrate specificity of the *E3* ligase. As a testament to their importance, there are more than 600 predicted ubiquitin ligase genes in the human genome. The many *E3* ligases in mammalian cells ensure that the wide variety of proteins to be polyubiquitinated can be modified when necessary. Some *E3* ligases are associated with chaperones that recognize unfolded or misfolded proteins; for example, the *E3* ligase *CHIP* is a co-chaperone for *Hsp70*. These and other proteins (co-chaperones, escort factors, adaptors) can mediate *E3*-ligase-catalyzed polyubiquitination of these dysfunctional proteins that cannot be readily refolded properly and their delivery to proteasomes for degradation. In such cases, the chaperone-ubiquitination-proteasome system works in concert for protein quality control.

In addition to quality control, the ubiquitin-proteasome system can be used to regulate the activity of important cellular proteins. An example is the regulated degradation of proteins called **cyclins**, which control the cell cycle (see Chapter 19). Cyclins contain the internal sequence Arg-X-X-Leu-Gly-X-Ile-Gly-Asp/Asn (X can be any amino acid), which is recognized by specific ubiquitinating enzyme complexes. At a specific time in the cell cycle, each cyclin is phosphorylated by a cyclin kinase. This phosphorylation is thought to cause a conformational change that exposes the recognition sequence to the ubiquitinating enzymes, leading to polyubiquitination and proteasomal degradation.

Other Functions of Ubiquitin and Ubiquitin-Related Molecules There are several close relatives of ubiquitin that employ similar *E1*-, *E2*-, and *E3*-dependent mechanisms of activation and transfer to acceptor substrates. These ubiquitin-like modifications control processes as diverse as nuclear import, regulated by the ubiquitin-like modifier *Sumo*, and autophagy,

regulated by the ubiquitin-like modifier Atg8/LC3 (see Chapter 14). The attachment of ubiquitin to a target protein can be used for purposes other than to mark the protein for degradation, as we will discuss later in this chapter, and some of these involve polyubiquitin linkages other than those via Lys48.

As is the case for ubiquitination itself, deubiquitination is involved in processes other than proteasome-mediated protein degradation. Large-scale, mass-spectroscopy-based “proteomic” methods described later in this chapter together with sophisticated computational approaches have suggested that Dubs, which are often bound in multiprotein complexes, are involved in an extraordinarily wide range of cell processes. These vary from cell division and cell cycle control (see Chapter 19) to membrane trafficking (see Chapter 14) to cell signaling pathways (see Chapters 15 and 16).

Noncovalent Binding Permits Allosteric, or Cooperative, Regulation of Proteins

In addition to regulating the amount of a protein, cells can also regulate the intrinsic activity of a protein. One of the most important mechanisms for regulating protein function is through allosteric interactions. Broadly speaking, **allostery** (from the Greek “other shape”) refers to any change in a protein’s tertiary or quaternary structure, or in both, induced by the noncovalent binding of a ligand. When a ligand binds to one site (A) in a protein and induces a conformational change and associated change in activity of a different site (B), the ligand is called an *allosteric effector* of the protein, while site A is called an *allosteric binding site*, and the protein is called an *allosteric protein*. By definition, allosteric proteins have multiple binding sites, at least one for the allosteric effector and at least one for other molecules with which the protein interacts. The allosteric change in activity can be positive or negative; that is, it can induce an increase or a decrease in protein activity. Negative allostery often involves the end product of a multistep biochemical pathway binding to and reducing the activity of an enzyme that catalyzes an early, rate-controlling step for that pathway. In this way excessive buildup of the product is prevented. This kind of regulation of a metabolic pathway is also called *end-product inhibition* or *feedback inhibition*. Allosteric regulation is particularly prevalent in multimeric enzymes and other proteins where conformational changes in one subunit are transmitted to an adjacent subunit.

Cooperativity is a term often used synonymously with allostery and usually refers to the influence (positive or negative) that the binding of a ligand at one site has on the binding of another molecule of the *same* type of ligand at a different site. Hemoglobin presents a classic example of positive cooperative binding in that the binding of a single ligand, molecular oxygen (O_2), increases the affinity of the binding of the next oxygen molecule. Each of the four subunits in hemoglobin contains one heme molecule. The heme groups are the oxygen-binding components of hemoglobin (see Figure 3-13). The binding of oxygen to the heme molecule in one of the four hemoglobin subunits induces a local

EXPERIMENTAL FIGURE 3-30 Hemoglobin binds oxygen cooperatively.

Each tetrameric hemoglobin protein has four oxygen-binding sites; at saturation all the sites are loaded with oxygen. The oxygen concentration in tissues is commonly measured as the partial pressure (pO_2). P_{50} is the pO_2 at which half the oxygen-binding sites at a given hemoglobin concentration are occupied; it is somewhat analogous to the K_m for an enzymatic reaction. The large change in the amount of oxygen bound over a small range of pO_2 values permits efficient unloading of oxygen in peripheral tissues such as muscle. The sigmoidal shape of a plot of percent saturation versus ligand concentration is indicative of cooperative binding, in which the binding of one oxygen molecule allosterically influences the binding of subsequent oxygens. In the absence of cooperative binding, a binding curve is a hyperbola, similar to the curves in Figure 3-22. [Adapted from L. Stryer, 1995, *Biochemistry*, 4th ed., W. H. Freeman and Company.]

conformational change whose effect spreads to the other subunits, lowering the K_d (increasing the affinity) for the binding of additional oxygen molecules to the remaining hemes and yielding a sigmoidal oxygen-binding curve (Figure 3-30). Because of the sigmoidal shape of the oxygen-saturation curve, it takes only a fourfold increase in oxygen concentration for the percent saturation of the oxygen-binding sites in hemoglobin to go from 10 to 90 percent. Conversely, if there were no cooperativity and the shape of the curve was typical of that for Michaelis-Menten-type, or noncooperative, binding, it would take an 81-fold increase in oxygen concentration to accomplish the same increase in loading of its binding sites in hemoglobin. This cooperativity permits hemoglobin to take up oxygen very efficiently in the lungs, where the oxygen concentration is high and unload it in tissues, where the concentration is low. Thus cooperativity amplifies the sensitivity of a system to concentration changes in its ligands, providing in many cases selective evolutionary advantage.

Noncovalent Binding of Calcium and GTP Are Widely Used as Allosteric Switches to Control Protein Activity

Unlike oxygen, which causes graded allosteric changes in the activity of hemoglobin, some other allosteric effectors act as

switches, turning the activity of many different proteins on or off by binding to them noncovalently. Two important allosteric switches that we will encounter many times throughout this book, especially in the context of cell signaling pathways (see Chapters 15 and 16), are Ca^{2+} and GTP.

Ca^{2+} /Calmodulin-Mediated Switching The concentration of Ca^{2+} free in the cytosol (not bound to molecules other than water) is kept very low ($\sim 10^{-7}$ M) by specialized membrane transport proteins that continually pump excess Ca^{2+} out of the cytosol. However, as we learn in Chapter 11, the cytosolic Ca^{2+} concentration can increase from 10- to 100-fold when Ca^{2+} -permeable channels in the cell-surface membranes open and allow extracellular Ca^{2+} to flow into the cell. This rise in cytosolic Ca^{2+} is sensed by specialized Ca^{2+} -binding proteins, which alter cellular behavior by turning the activities of other proteins on or off. The importance of extracellular Ca^{2+} for cell activity was first documented by S. Ringer in 1883, when he discovered that isolated rat hearts suspended in an NaCl solution made with “hard” (Ca^{2+} -rich) London tap water contracted beautifully, whereas they beat poorly and stopped quickly if distilled water was used.

Many of the Ca^{2+} -binding proteins bind Ca^{2+} using the EF hand/helix-loop-helix structural motif discussed earlier (see Figure 3-9b). A well-studied EF hand protein, calmodulin, is found in all eukaryotic cells and may exist as an individual monomeric protein or as a subunit of a multimeric protein. A dumbbell-shaped molecule, calmodulin contains four Ca^{2+} -binding EF hands with K_d 's of $\sim 10^{-6}$ M. The binding of Ca^{2+} to calmodulin causes a conformational change that permits Ca^{2+} /calmodulin to bind to conserved sequences in various target proteins (Figure 3-31), thereby switching their activities on or off. Calmodulin and similar EF hand proteins thus function as *switch proteins*, acting in concert with changes in Ca^{2+} levels to modulate the activity of other proteins.

Switching Mediated by Guanine-Nucleotide-Binding Proteins Another group of intracellular switch proteins constitutes the **GTPase superfamily**. As the name suggests, these proteins are enzymes, GTPases, that can hydrolyze GTP (guanosine triphosphate) to GDP (guanosine diphosphate). They include the monomeric Ras protein, whose structure is shown in Figure 3-8 with bound GDP shown in blue, and the G_α subunit of the trimeric G proteins, both discussed at length in Chapters 15 and 16. Both Ras and G_α can bind to the plasma membrane, function in cell signaling, and play a key role in cell proliferation and differentiation. Other members of the GTPase superfamily function in protein synthesis, the transport of proteins between the nucleus and the cytoplasm, the formation of coated vesicles and their fusion with target membranes, and rearrangements of the actin cytoskeleton. The Hsp70 chaperone protein we encountered earlier is an example of an ATP/ADP switch, similar in many respects to a GTP/GDP switch.

All the GTPase switch proteins exist in two forms, or conformations (Figure 3-32): (1) an active (“on”) form with bound GTP that can influence the activity of specific target

(a) Calmodulin without calcium

(b) Ca^{2+} /calmodulin bound to target peptide

FIGURE 3-31 Conformational changes induced by Ca^{2+} binding to calmodulin. Calmodulin is a widely distributed cytosolic protein that contains four Ca^{2+} -binding sites, one in each of its EF hands. Each EF hand has a helix-loop-helix motif. At cytosolic Ca^{2+} concentrations above about 5×10^{-7} M, binding of Ca^{2+} to calmodulin changes the protein's conformation from the dumbbell-shaped, unbound form (a) to one in which hydrophobic side chains become more exposed to solvent. The resulting Ca^{2+} -calmodulin can wrap around exposed helices of various target proteins (b), thereby altering their activity.

proteins to which they bind and (2) an inactive (“off”) form with bound GDP. The switch is turned on, that is, the conformation of the protein changes from inactive to active, when a GTP molecule replaces a bound GDP in the inactive conformation. The switch is turned off when the relatively slow GTPase activity of the protein hydrolyzes bound GTP, converting it to GDP and leading the conformation to change to the inactive form. The amount of time any given GTPase switch remains in the active, GTP-bound form depends on how long the GTP remains bound before it is converted to GDP. This time depends on the rate of the GTPase activity. Thus the GTPase activity acts as a timer to control this switch. Cells contain a variety of proteins that can modulate the baseline (or intrinsic) rate of GTPase activity for any given GTPase switch and so can control how long the switch remains on. Cells also have specific proteins whose function is to regulate the conversion of inactive GTPases to active ones—that is, turn the switch on—by mediating the replacement of bound GDP with a GTP. These are called GTP exchange factors, or GEFs. We examine the role of various GTPase switch proteins in regulating intracellular signaling and other processes in several later chapters.

FIGURE 3-32 The GTPase switch. GTPases are enzymes that bind to and hydrolyze GTP to GDP. When bound to GTP, the GTPase protein adopts its active or “on” conformation and can interact with target proteins to regulate their activities; when the bound GTP is hydrolyzed to GDP by the intrinsic GTPase activity of the protein, the GTPase with GDP bound assumes an inactive or “off” conformation. The GTPase switch can be turned back on when another protein, called a GEF (guanine nucleotide exchange factor), mediates the replacement of the bound GDP with a GTP molecule from the surrounding fluid. The binding of the active form of the GTPases to its targets is a form of noncovalent regulation. Various proteins can influence the rates of GTP hydrolysis (i.e., inactivator proteins) and exchange of GDP for GTP (GEFs).

Phosphorylation and Dephosphorylation Covalently Regulate Protein Activity

In addition to exploiting the noncovalent regulators described above, cells can use covalent modifications to regulate the intrinsic activity of a protein. One of the most common covalent mechanisms for regulating protein activity is **phosphorylation**, the reversible addition of phosphate groups to hydroxyl groups on the side chains of serine, threonine, or tyrosine residues. Phosphorylation is catalyzed by enzymes called **protein kinases**, while the removal of phosphates, known as **dephosphorylation**, is catalyzed by **phosphatases**. The counteracting activities of kinases and phosphatases provide cells with a “switch” that can turn on or turn off the function of various proteins (Figure 3-33). Sometimes phosphorylation sites are masked transiently by the reversible covalent modification with the sugar N-acetylglucosamine as an additional means of regulation. Phosphorylation changes a protein’s charge and can lead to a

conformational change that can significantly alter ligand binding or other features of the protein, causing an increase or decrease in its activity. In addition, several conserved protein domains specifically bind to phosphorylated peptides. Thus phosphorylation can mediate the formation of protein complexes that can generate or extinguish a wide variety of cellular activities, discussed in many subsequent chapters.

Nearly 3 percent of all yeast proteins are protein kinases or phosphatases, indicating the importance of phosphorylation and dephosphorylation reactions even in simple cells. All classes of proteins—including structural proteins, scaffolds, enzymes, membrane channels, and signaling molecules—have members regulated by kinase/phosphatase modifications. Different protein kinases and phosphatases are specific for different target proteins and so can regulate distinct cellular pathways, as discussed in later chapters. Some kinases have many targets and so a single kinase can serve to integrate the activities of many targets simultaneously. Frequently, the target of the kinase (and phosphatase) is yet another kinase or phosphatase, creating a cascade effect. There are many examples of such kinase cascades, which permit amplification of a signal and many levels of fine-tuning control (see Chapters 15 and 16).

FIGURE 3-33 Regulation of protein activity by phosphorylation and dephosphorylation. The cyclic phosphorylation and dephosphorylation of a protein is a common cellular mechanism for regulating protein activity. In this example, the target protein is active (top) when phosphorylated and inactive (bottom) when dephosphorylated; some proteins have the opposite response to phosphorylation.

Ubiquitination and Deubiquitination Covalently Regulate Protein Activity

Both ubiquitin and ubiquitin-like proteins (of which there are more than a dozen in humans) can be covalently linked to a target protein in a regulated fashion, analogously to phosphorylation. Deubiquitinases can reverse ubiquitination, analogously to the action of phosphatases. These ubiquitin modifications are structurally far more complex than relatively simple phosphorylation, however, and so can mediate many distinct interactions between the ubiquitinated protein and other cellular proteins. Ubiquitination can involve attachment of a single ubiquitin to a protein (**monoubiquitination**), addition of multiple, single ubiquitin molecules to different sites on one target protein (**multiubiquitination**), or addition of a polymeric chain of ubiquitins to a protein (**polyubiquitination**). An additional source of variation is that

FIGURE 3-34 Determination of polyubiquitin function by the lysine used for inter-ubiquitin isopeptide bonds. Different ubiquitin ligases catalyze polyubiquitination of distinct target (substrate) proteins (colored ovals) using distinct lysine side chains of ubiquitin molecules (purple) to generate the inter-ubiquitin isopeptide linkages (blue) with Gly76 of the adjacent ubiquitin. Dotted blue arrows represent additional ubiquitins in the chain that are not shown.

The lysine used for the isopeptide bonds determines the function of the polyubiquitination. For example, polyubiquitins with Lys48:Gly76 isopeptide bonds direct the target to proteasomes for degradation. Those with Lys63, Lys33, and Lys11 influence signaling, T-lymphocyte control, and cell division, respectively. Isopeptide bonds involving ubiquitin's Lys6, Lys27, and Lys29 and bonds using its N-terminal amino group (not shown) can also be used to generate polyubiquitin chains.

different amino groups in the ubiquitin can be used to form an isopeptide bond with the carboxy terminal Gly76 in an adjacent ubiquitin in a polyubiquitin chain. All seven lysine residues in ubiquitin (Lys6, Lys11, Lys27, Lys29, Lys33, Lys48, and Lys63) and the N-terminal amino group of ubiquitin can participate in inter-ubiquitin linkages. Different ubiquitin ligases exhibit specificity for both the target (substrate) to be ubiquitinated and the lysine side chains on the ubiquitins that participate in the inter-ubiquitin isopeptide linkages (Lys63 or Lys 48, etc.) (Figure 3-34). These multiple forms of ubiquitination result in the generation of a wide variety of recognition surfaces that can participate in many protein-protein interactions with the hundreds of proteins (>200 in humans) that contain more than a dozen distinct ubiquitin-binding domains (UBD). In addition, any given polyubiquitin chain has the potential to bind simultaneously more than one UBD-containing protein, leading to the formation of ubiquitination-dependent multiprotein complexes. Some deubiquitinases can remove an intact polyubiquitin chain from a modified protein ("anchored" chain) and thus generate a polyubiquitin chain not covalently linked to another protein ("unanchored" chain). Even these unanchored chains may serve a regulatory

role. With this great structural diversity, it is not surprising that cells use ubiquitination and deubiquitination to control many different cellular functions.

We have already seen how polyubiquitination via Lys48 residues is used to tag proteins for proteasomal degradation. Ubiquitination unrelated to protein degradation also can control diverse cell functions, including repair of damaged DNA, metabolism, messenger RNA synthesis (transcription), defense against pathogens, cell division/cell cycle progression, cell signaling pathways, trafficking of proteins within a cell, and programmed cell death (apoptosis). The lysine used to form the inter-ubiquitin isopeptide bonds can vary depending on the cellular system that is regulated (see Figure 3-34). For example, polyubiquitination with Lys63 linkages is used in many cellular identification and signaling systems, such as recognition of the presence of intracellular viral RNA and the consequent induction of a protective immune response. Lys11-linked polyubiquitin chains regulate cell division. Lys33-linked chains help suppress the activity of receptors on specialized white blood cells, called T lymphocytes (see Chapter 23), and so control the activity and function of the lymphocytes that bear these receptors.

Proteolytic Cleavage Irreversibly Activates or Inactivates Some Proteins

Unlike phosphorylation and ubiquitination, which are reversible, the activation or inactivation of protein function by proteolytic cleavage is an irreversible mechanism for regulating protein activity. For example, many polypeptide hormones, such as insulin, are synthesized as longer precursors, and prior to secretion from cells some of their peptide bonds must be hydrolyzed for them to fold properly. In some cases, a single long precursor *prohormone* polypeptide can be cleaved into several distinct active hormones. To prevent the pancreatic serine proteases from inappropriately digesting proteins before they reach the small intestines, they are synthesized as *zymogens*, inactive precursor enzymes. Cleavage of a peptide bond near the N-terminus of trypsinogen (the zymogen of trypsin) by a highly specific protease in the small intestine generates a new N-terminal residue (Ile-16), whose amino group can form an ionic bond with the carboxylic acid side chain of an internal aspartic acid. This causes a conformation change that opens the substrate-binding site, activating the enzyme. The active trypsin can then activate trypsinogen, chymotrypsinogen, and other zymogens. Similar but more elaborate protease cascades (one protease activating inactive precursors of others) that can amplify an initial signal play important roles in several systems, such as the blood-clotting cascade and the complement system (see Chapter 23). The importance of carefully regulating such systems is clear—inappropriate clotting could fatally clog the circulatory system, while insufficient clotting could lead to uncontrolled bleeding.

An unusual and rare type of proteolytic processing, termed *protein self-splicing*, takes place in bacteria and some eukaryotes. This process is analogous to editing film: an internal segment of a polypeptide is removed and the ends of the polypeptide are rejoined (ligated). Unlike other forms of proteolytic processing, protein self-splicing is an autocatalytic process, which proceeds by itself without the participation of other enzymes. The excised peptide appears to eliminate itself from the protein by a mechanism similar to that used in the processing of some RNA molecules (see Chapter 8). In vertebrate cells, the processing of some proteins includes self-cleavage, but the subsequent ligation step is absent. One such protein is Hedgehog, a membrane-bound signaling molecule that is critical to a number of developmental processes (see Chapter 16).

Higher-Order Regulation Includes Control of Protein Location and Concentration

All the regulatory mechanisms heretofore described affect a protein locally at its site of action, turning its activity on or off. Normal functioning of a cell, however, also requires the segregation of proteins to particular compartments such as the mitochondria, nucleus, and lysosomes. In regard to enzymes, compartmentation not only provides an opportunity for controlling the delivery of substrate or the exit of product but also permits competing reactions to take place simulta-

neously in different parts of a cell. We describe the mechanisms that cells use to direct various proteins to different compartments in Chapters 13 and 14.

KEY CONCEPTS of Section 3.4

Regulating Protein Function

- Proteins may be regulated at the level of protein synthesis, protein degradation, or the intrinsic activity of proteins through noncovalent or covalent interactions.
- The life span of intracellular proteins is largely determined by their susceptibility to proteolytic degradation.
- Many proteins are marked for destruction with a polyubiquitin tag by ubiquitin ligases and then degraded within proteasomes, large cylindrical complexes with multiple protease active sites in their interior chambers (see Figure 3-29).
- Ubiquitination of proteins is reversible due to the activity of deubiquitinating enzymes.
- In allostery, the noncovalent binding of one ligand molecule, the allosteric effector, induces a conformational change that alters a protein's activity or affinity for other ligands. The allosteric effector can be identical in structure to or different from the other ligands, whose binding it affects. The allosteric effector can be an activator or an inhibitor.
- In multimeric proteins, such as hemoglobin, that bind multiple identical ligand molecules (e.g., oxygen), the binding of one ligand molecule may increase or decrease the binding affinity for subsequent ligand molecules. This type of allostery is known as cooperativity (see Figure 3-30).
- Several allosteric mechanisms act as switches, turning protein activity on and off in a reversible fashion.
- Two classes of intracellular switch proteins regulate a variety of cellular processes: (1) Ca^{2+} -binding proteins (e.g., calmodulin) and (2) members of the GTPase superfamily (e.g., Ras), which cycle between active GTP-bound and inactive GDP-bound forms (see Figure 3-32).
- The phosphorylation and dephosphorylation of hydroxyl groups on serine, threonine, or tyrosine residue side chains by protein kinases and phosphatases provide reversible on/off regulation of numerous proteins (see Figure 3-33).
- Variations in the nature of the covalent attachment of ubiquitin to proteins (mono-, multi-, and polyubiquitination involving a variety of linkages between the ubiquitin monomers) are involved in a wide variety of cellular functions other than proteasome-mediated degradation, such as changes in the location or activity of proteins (see Figure 3-34).
- Many types of covalent and noncovalent regulation are reversible, but some forms of regulation, such as proteolytic cleavage, are irreversible.
- Higher-order regulation includes compartmentation of proteins and control of protein concentration.

3.5 Purifying, Detecting, and Characterizing Proteins

A protein often must be purified before its structure and the mechanism of its action can be studied in detail. However, because proteins vary in size, shape, oligomerization state, charge, and water solubility, no single method can be used to isolate all proteins. To isolate one particular protein from the estimated 10,000 different proteins in a particular type of cell is a daunting task that requires methods both for separating proteins and for detecting the presence of specific proteins.

Any molecule, whether protein, carbohydrate, or nucleic acid, can be separated, or *resolved*, from other molecules on the basis of their differences in one or more physical or chemical characteristics. The larger and more numerous the differences between two proteins, the easier and more efficient their separation. The three most widely used characteristics for separating proteins are *size*, defined as either length or mass; net electrical charge; and *binding affinity* for specific ligands. In this section, we briefly outline several important techniques for separating proteins; these separation techniques are also useful for the separation of nucleic acids and other biomolecules. (Specialized methods for removing membrane proteins from membranes are described in Chapter 10 after the unique properties of these proteins are discussed.) We then consider the use of radioactive compounds for tracking biological activity. Finally, we consider several techniques for characterizing a protein's mass, sequence, and three-dimensional structure.

Centrifugation Can Separate Particles and Molecules That Differ in Mass or Density

The first step in a typical protein purification scheme is centrifugation. The principle behind centrifugation is that two particles in suspension (cells, cell fragments, organelles, or molecules) with different masses or densities will settle to the bottom of a tube at different rates. Remember, mass is the weight of a sample (measured in daltons or molecular weight units), whereas density is the ratio of its mass to volume (often expressed as grams/liter because of the methods used to measure density). Proteins vary greatly in mass but not in density. Unless a protein has an attached lipid or carbohydrate, its density will not vary by more than 15 percent from 1.37 g/cm³, the average protein density. Heavier or more dense molecules settle, or sediment, more quickly than lighter or less dense molecules.

A centrifuge speeds sedimentation by subjecting particles in suspension to centrifugal forces as great as 1 million times the force of gravity, *g*, which can sediment particles as small as 10 kDa. Modern ultracentrifuges achieve these forces by reaching speeds of 150,000 revolutions per minute (rpm) or greater. However, small particles with masses of 5 kDa or less will not sediment uniformly even at such remarkably high rotation rates. The extraordinary technical achievements of modern ultracentrifuges can be appreciated by considering that they can rotate a several-pound rotor (about

the size of an American football) that holds the samples in tubes at rates as high as 2500 revolutions per second!

Centrifugation is used for two basic purposes: (1) as a preparative technique to separate one type of material from others and (2) as an analytical technique to measure physical properties (e.g., molecular weight, density, shape, and equilibrium binding constants) of macromolecules. The sedimentation constant, *s*, of a protein is a measure of its sedimentation rate. The sedimentation constant is commonly expressed in svedbergs (S), where a typical, large protein complex is about 3–5S, a proteasome is 26S, and a eukaryotic ribosome is 80S.

Differential Centrifugation The most common initial step in protein purification from cells or tissues is the separation of water-soluble proteins from insoluble cellular material by *differential centrifugation*. A starting mixture, commonly a cell homogenate (mechanically broken cells), is poured into a tube and spun at a rotor speed and for a period of time that forces cell organelles such as nuclei and large unbroken cells or large cell fragments to collect as a pellet at the bottom; the soluble proteins remain in the supernatant (Figure 3-35a). The supernatant fraction then is poured off, and either it or the pellet can be subjected to other purification methods to separate the many different proteins that they contain.

Rate-Zonal Centrifugation On the basis of differences in their masses, water-soluble proteins can be separated by centrifugation through a solution of increasing density called a *density gradient*. A concentrated sucrose solution is commonly used to form density gradients. When a protein mixture is layered on top of a sucrose gradient in a tube and subjected to centrifugation, each protein in the mixture migrates down the tube at a rate controlled by the factors that affect the sedimentation constant. All the proteins start from a thin zone at the top of the tube and separate into bands (actually, disks) of proteins of different masses. In this separation technique, called *rate-zonal centrifugation*, samples are centrifuged just long enough to separate the molecules of interest into discrete bands (Figure 3-35b). If a sample is centrifuged for too short a time, the different protein molecules will not separate sufficiently. If a sample is centrifuged much longer than necessary, all the proteins will end up in a pellet at the bottom of the tube.

Although the sedimentation rate is strongly influenced by particle mass, rate-zonal centrifugation is seldom effective in determining precise molecular weights because variations in shape also affect sedimentation rate. The exact effects of shape are hard to assess, especially for proteins or other molecules, such as single-stranded nucleic acid molecules, that can assume many complex shapes. Nevertheless, rate-zonal centrifugation has proved to be a practical method for separating many different types of polymers and particles. A second density-gradient technique, called *equilibrium density-gradient centrifugation*, is used mainly to separate DNA, lipoproteins that carry lipids through the circulatory system, or organelles (see Figure 9-35).

EXPERIMENTAL FIGURE 3-35
Centrifugation techniques separate particles that differ in mass or density.

(a) In differential centrifugation, a cell homogenate or other mixture is spun long enough to sediment the larger particles (e.g., cell organelles, cells), which collect as a pellet at the bottom of the tube (step 2). The smaller particles (e.g., soluble proteins, nucleic acids) remain in the liquid supernatant, which can be transferred to another tube (step 3). (b) In rate-zonal centrifugation, a mixture is spun (step 1) just long enough to separate molecules that differ in mass but may be similar in shape and density (e.g., globular proteins, RNA molecules) into discrete zones within a density gradient commonly formed by a concentrated sucrose solution. Fractions are removed from the bottom of the tube and subjected to testing (assayed).

Electrophoresis Separates Molecules on the Basis of Their Charge-to-Mass Ratio

Electrophoresis is a technique for separating molecules in a mixture under the influence of an applied electric field and is one of the most frequently used techniques to study proteins and nucleic acids. Dissolved molecules in an electric field move, or migrate, at a speed determined by their charge-to-mass (charge:mass) ratio and the physical properties of the medium through which they migrate. For example, if two molecules have the same mass and shape, the one with the greater net charge will move faster toward an electrode of the opposite polarity.

SDS-Polyacrylamide Gel Electrophoresis Because many proteins or nucleic acids that differ in size and shape have nearly identical charge:mass ratios, electrophoresis of these macromolecules in solution results in little or no separation of molecules of different lengths. However, successful separation of proteins and nucleic acids can be accomplished by electrophoresis in various gels (semisolid suspensions in water similar to

the congealed gelatin found in desserts) rather than in a liquid solution. Electrophoretic separation of proteins is most commonly performed in polyacrylamide gels. When a mixture of proteins is placed in a gel and an electric current is applied, smaller proteins migrate faster through the gel than do larger proteins because the gel acts as a sieve, with smaller species able to maneuver more rapidly through the pores in the gel than larger species. The shape of a molecule can also influence its rate of migration (long asymmetric molecules migrate more slowly than spherical ones of the same mass).

Gels are cast into flat, relatively thin slabs between a pair of glass plates by polymerizing a solution of acrylamide monomers into polyacrylamide chains and simultaneously cross-linking the chains into a semisolid matrix. The pore size of a gel can be varied by adjusting the concentrations of polyacrylamide and the cross-linking reagent. The rate at which a protein moves through a gel is influenced by the gel's pore size and the strength of the electric field. By suitable adjustment of these parameters, proteins of widely varying sizes can be resolved (separated from one another) by polyacrylamide gel electrophoresis (PAGE).

EXPERIMENTAL FIGURE 3-36 SDS-polyacrylamide gel electrophoresis (SDS-PAGE) separates proteins primarily on the basis of their masses. (a) Initial treatment with SDS, a negatively charged detergent, dissociates multimeric proteins and denatures all the polypeptide chains (step 1). During electrophoresis, the SDS-protein complexes migrate through the polyacrylamide gel (step 2). Small complexes are able to move through the pores faster than larger ones. Thus the proteins separate into bands according to their sizes as they migrate. The separated protein bands are visualized by staining with a dye (step 3). (b) Example of SDS-PAGE separation of all the proteins in a whole-cell lysate (detergent solubilized cells): (left) the many separate stained proteins, appearing almost as a continuum; (right) a protein purified from the lysate by a single step of antibody-affinity chromatography. The proteins were visualized by staining with a silver-based dye. [Part (b) modified from B. Liu and M. Krieger, 2002, *J. Biol. Chem.* 277(37):34125–34135.]

In the most powerful technique for resolving protein mixtures, proteins are exposed to the ionic detergent SDS (sodium dodecylsulfate) before and during gel electrophoresis (Figure 3-36). SDS denatures proteins, in part because it binds to hydrophobic side chains, destabilizing the hydrophobic interactions in the core of a protein that contribute to its stable conformation. (SDS treatment is usually combined with heating, often in the presence of reducing agents that break disulfide bonds.) Under these conditions, multimeric proteins dissociate into their subunits, and typically the amount of SDS that binds to the protein is proportional to the length of the polypeptide chain and relatively independent of the sequence. Two proteins of similar size will bind the same absolute quantity of SDS, whereas a protein twice that size will bind twice the amount of SDS. Denaturation of a complex protein mixture with SDS in combination with heat usually forces each polypeptide chain into an extended conformation and imparts on each of the proteins in the mixture a constant mass/charge ratio because the dodecylsulfate is negatively charged. As the SDS-bound proteins move through the polyacrylamide gel, they are separated according to size by the sieving action of the gel. SDS treatment thus eliminates the effect of differences in shape in native structures; therefore, chain length, which corresponds to mass, is the principal determinant of the migration rate of proteins in *SDS-polyacrylamide electrophoresis* (*SDS-PAGE*). Even chains that differ in molecular weight by less than 10 percent can be resolved by this technique. Moreover, the molecular weight of a protein can be estimated by comparing the distance that it migrates through a gel with the distances that proteins of known molecular weight migrate (there is roughly a linear relationship between migration distance and the log of the molecular weight). Proteins within the gels can be extracted for further analysis (e.g., identification by methods described below).

Two-Dimensional Gel Electrophoresis Electrophoresis of all cellular proteins by SDS-PAGE can separate proteins having

relatively large differences in mass but cannot readily resolve proteins having similar masses (e.g., a 41-kDa protein versus a 42-kDa protein). To separate proteins of similar masses, another physical characteristic must be exploited. Most commonly, this characteristic is electric charge, which is determined by the pH and the relative number of the protein's positively and negatively charged groups, which is in turn dependent on the pK_a 's of the ionizable groups (see Chapter 2). Two unrelated proteins having similar masses are unlikely to have identical net charges because their sequences, and thus the number of acidic and basic residues, are different.

In two-dimensional electrophoresis, proteins are separated sequentially, first by their charges and then by their masses (Figure 3-37a). In the first step, a cell or tissue extract is fully denatured by high concentrations (8 M) of urea (and sometimes SDS) and then layered on a gel strip that contains urea, which removes any bound SDS, and a continuous pH gradient. The pH gradient is formed by ampholytes, a mixture of polyanionic and polycationic small molecules, that

EXPERIMENTAL FIGURE 3-37 Two-dimensional gel electrophoresis separates proteins on the basis of charge and mass. (a) In this technique, proteins are first separated into bands on the basis of their charges by isoelectric focusing (step 1). The resulting gel strip is applied to an SDS-polyacrylamide gel (step 2), and the proteins are separated

are cast into the gel. When an electric field is applied to the gel, ampholytes will migrate, so that ampholytes with an excess of negative charges will migrate toward the anode, where they establish an acidic pH (many protons), while ampholytes with an excess positive charge will migrate toward the cathode, where they establish an alkaline pH. The careful choice of the mixture of ampholytes and the preparation of the gel allows the construction of stable pH gradients anywhere from pH 3 to pH 10. A charged protein placed onto one end of such a gel will migrate through the gradient until it reaches its **isoelectric point (pI)**, the pH at which the net charge of the protein is zero. With no net charge, the protein will not migrate under the influence of the electric field. This technique, called *isoelectric focusing (IEF)*, can resolve proteins that differ by only one charge unit. Proteins that have been separated on an IEF gel can then be separated in a second dimension on the basis of their molecular weights. To accomplish this separation, the IEF gel strip is placed lengthwise on one outside edge of a sheet-like (two-dimensional, or slab) polyacrylamide gel, this time saturated with SDS to confer on each separated protein a more or less constant mass:charge ratio. When an electric field is imposed, the proteins will migrate from the IEF gel into the SDS slab gel and then separate according to their masses.

The sequential resolution of proteins by charge and mass can achieve excellent separation of cellular proteins (Figure 3-37b). For example, two-dimensional gels have been very useful in comparing the proteomes in undifferentiated and differ-

into spots by mass (step 3). (b) In this two-dimensional gel of a protein extract from cultured cells, each spot represents a single polypeptide. Polypeptides can be detected by dyes, as here, or by other techniques such as autoradiography. Each polypeptide is characterized by its isoelectric point (pI) and molecular weight. [Part (b) courtesy of J. Celis.]

entiated cells or in normal and cancer cells because as many as 1000 proteins can be resolved as individual spots simultaneously. Unfortunately, membrane proteins separate relatively poorly using this technique. Sophisticated methods have been developed to permit the comparison of complex patterns of proteins in two-dimensional gels from related, but distinct, samples (e.g., tissue from a normal versus a mutant individual) to permit identification of differences in the types or amounts of proteins in the samples (see Section 3.6, on proteomics, below). Sophisticated mass spectrometry methods, described below, are often used in place of two-dimensional gel electrophoresis to identify the protein components of a complex sample.

Liquid Chromatography Resolves Proteins by Mass, Charge, or Binding Affinity

A third common technique for separating mixtures of proteins or fragments of proteins, as well as other molecules, is based on the principle that molecules dissolved in a solution can differentially interact (bind and dissociate) with a particular solid surface, depending on the physical and chemical properties of the molecule and the surface. If the solution is allowed to flow across the surface, then molecules that interact frequently with the surface will spend more time bound to the surface and thus flow past the surface more slowly than molecules that interact infrequently with it. In this technique, called **liquid chromatography (LC)**, the sample is placed on top of a tightly packed column of spherical beads held within

a glass or plastic cylinder. The sample then flows down the column, usually driven by gravitational or hydrostatic forces alone or with the assistance of a pump, and small aliquots of fluid flowing out of the column, called *fractions*, are collected sequentially for subsequent analysis for the presence of the proteins of interest. The nature of the beads in the column determines whether the separation of proteins depends on differences in mass, charge, or binding affinity.

Gel Filtration Chromatography Proteins that differ in mass can be separated on a column composed of porous beads made from polyacrylamide, dextran (a bacterial polysaccharide), or agarose (a seaweed derivative)—a technique called gel filtration chromatography. Although proteins flow around the spherical beads in gel filtration chromatography, they spend some time within the large depressions that cover a bead's surface. Because smaller proteins can penetrate into these depressions more readily than larger proteins can, they travel through a gel filtration column more slowly than larger proteins (Figure 3-38a). (In contrast, proteins migrate *through* the pores in an electrophoretic gel; thus smaller proteins move faster than larger ones.) The total volume of liquid required to elute (or separate and remove) a protein from a gel filtration column depends on its mass: the smaller the mass, the more time it is trapped on the beads, the greater the elution volume. By use of proteins of known mass as standards to calibrate the column, the elution volume can be used to estimate the mass of a protein in a mixture. A protein's shape as well as its mass can influence the elution volume.

Ion-Exchange Chromatography In ion-exchange chromatography, a second type of liquid chromatography, proteins are separated on the basis of differences in their charges. This technique makes use of specially modified beads whose surfaces are covered by amino groups or carboxyl groups and thus carry either a positive charge (NH_3^+) or a negative charge (COO^-) at neutral pH.

The proteins in a mixture carry various net charges at any given pH. When a solution of a protein mixture flows through a column of positively charged beads, only proteins with a net negative charge (acidic proteins) adhere to the beads; neutral and positively charged (basic) proteins flow unimpeded through the column (Figure 3-38b). The acidic proteins are then eluted selectively from the column by passing a solution of increasing concentrations of salt (a salt gradient) through the column. At low salt concentrations, protein molecules and beads are attracted by their opposite charges. At higher salt concentrations, negative salt ions bind to the positively charged beads, displacing the negatively charged proteins. In a gradient of increasing salt concentration, weakly bound proteins, those with relatively low charge, are eluted first and highly charged proteins are eluted last. Similarly, a negatively charged column can be used to retain and fractionate basic (positively charged) proteins.

Affinity Chromatography The ability of proteins to bind specifically to other molecules is the basis of affinity chroma-

tography. In this technique, ligand or other molecules that bind to the protein of interest are covalently attached to the beads used to form the column. Ligands can be enzyme substrates, inhibitors or their analogs, or other small molecules that bind to specific proteins. In a widely used form of this technique—*antibody-affinity*, or *immunoaffinity chromatography*—the attached molecule is an antibody specific for the desired protein (Figure 3-38c). (We discuss antibodies as tools to study proteins next; see also Chapter 23, which describes how antibodies are made.)

An affinity column in principle will retain only those proteins that bind the molecule attached to the beads; the remaining proteins, regardless of their charges or masses, will pass through the column because they do not bind. However, if a retained protein is in turn bound to other molecules, forming a complex, then the entire complex is retained on the column. The proteins bound to the affinity column are then eluted by adding an excess of a soluble form of the ligand, by exposure of bound materials to detergents, or by changing the salt concentration or pH such that the binding to the molecule on the column is disrupted. The ability of this technique to separate particular proteins depends on the selection of appropriate binding partners that bind more tightly to the protein of interest than to other proteins.

Highly Specific Enzyme and Antibody Assays Can Detect Individual Proteins

The purification of a protein, or any other molecule, requires a specific assay that can detect the presence of the molecule of interest as it is separated from other molecules (e.g., in column or density-gradient fractions or gel bands or spots). An assay capitalizes on some highly distinctive characteristic of a protein: the ability to bind a particular ligand, to catalyze a particular reaction, or to be recognized by a specific antibody. An assay must also be simple and fast to minimize errors and the possibility that the protein of interest becomes denatured or degraded while the assay is performed. The goal of any purification scheme is to isolate sufficient amounts of a given protein for study; thus a useful assay must also be sensitive enough that only a small proportion of the available material is consumed by it. Many common protein assays require just 10^{-9} to 10^{-12} g of material.

Chromogenic and Light-Emitting Enzyme Reactions Many assays are tailored to detect some functional aspect of a protein. For example, enzymatic activity assays are based on the ability to detect the loss of substrate or the formation of product. Some enzymatic assays utilize chromogenic substrates, which change color in the course of the reaction. (Some substrates are naturally chromogenic; if they are not, they can be linked to a chromogenic molecule.) Because of the specificity of an enzyme for its substrate, only samples that contain the enzyme will change color in the presence of a chromogenic substrate; the rate of the reaction provides a measure of the quantity of enzyme present. Enzymes that catalyze chromogenic reactions can also be fused or chemically linked to an

(a) Gel filtration chromatography

(c) Antibody-affinity chromatography

(b) ion-exchange chromatography

EXPERIMENTAL FIGURE 3-38 Three commonly used liquid chromatographic techniques separate proteins on the basis of mass, charge, or affinity for a specific binding partner.

(a) Gel filtration chromatography separates proteins that differ in size. A mixture of proteins is carefully layered on the top of a cylinder packed with porous beads. Smaller proteins travel through the column more slowly than larger proteins. Thus different proteins emerging in the eluate flowing out of the bottom of the column at different times (different elution volumes) can be collected in separate tubes, called *fractions*.

(b) Ion-exchange chromatography separates proteins that differ in net charge in columns packed with special beads that carry either a positive charge (shown here) or a negative charge. Proteins having the same net charge as the beads are repelled and flow through the column, whereas

proteins having the opposite charge bind to the beads more or less tightly, depending on their structures. Bound proteins—in this case, negatively charged—are subsequently eluted by passing a salt gradient (usually of NaCl or KCl) through the column. As the ions bind to the beads, they displace the proteins (more tightly bound proteins require higher salt concentration in order to be released). (c) In antibody-affinity chromatography, a mixture of proteins is passed through a column packed with beads to which a specific antibody is covalently attached. Only protein with high affinity for the antibody is retained by the column; all the nonbinding proteins flow through. After the column is washed, the bound protein is eluted with an acidic solution or some other solution that disrupts the antigen-antibody complexes; the released protein then flows out of the column and is collected.

antibody and used to “report” the presence or location of an antigen to which the antibody binds (see below).

Antibody Assays As noted earlier, antibodies have the distinctive characteristic of binding tightly and specifically to antigens. As a consequence, preparations of antibodies that

recognize a protein antigen of interest can be generated and used to detect the presence of the protein, either in a complex mixture of other proteins (finding a needle in a haystack, as it were) or in a partially purified preparation of a particular protein. An antibody molecule will generally only bind tightly to a small part of a target molecule (antigen) that exhibits

molecular complementarity with the antibody. This antibody-binding region of the target is called the antibody's cognate epitope, or simply epitope. Thus the presence of the antigen that contains an epitope can be visualized by labeling the antibody with an enzyme, a fluorescent molecule, or radioactive isotopes. For example, luciferase, an enzyme present in fireflies and some bacteria, can be linked to an antibody. In the presence of ATP and the substrate luciferin, luciferase catalyzes a light-emitting reaction. In either case, after the antibody binds to the protein of interest (the antigen) and unbound antibody is washed away, substrates of the linked enzyme are added and the appearance of color or emitted light is monitored. The intensity is proportional to the amount of enzyme-linked antibody, and thus antigen, in the sample. A variation of this technique, particularly useful in detecting specific proteins within living cells, makes use of *green fluorescent protein* (GFP), a naturally fluorescent protein found in jellyfish (see Figure 9-15). Alternatively, after the first antibody that is not otherwise labeled binds to its target protein, a second, labeled antibody that can recognize the first antibody is used to bind to the complex of the first antibody and its target. This combination of two antibodies permits very high sensitivity in the detection of a target protein because the labeled second antibody is often a mixture of antibodies that bind to multiple sites on the first antibody. It is important to remember that an antibody binds to or recognizes its cognate epitope on a target antigen. If that epitope is altered, for example by partial unfolding or post-translational modifications, or is blocked when the antigen protein is bound to some other molecule, the ability of the antibody to bind may be reduced or completely lost. Thus the absence of antibody binding does not necessarily mean the antigen is not present in a sample, only that the epitope is not present or accessible for binding.

To generate the antibodies, the intact protein or a fragment of the protein is injected into an animal (usually a rabbit, mouse, or goat). Sometimes a short synthetic peptide of 10–15 residues based on the sequence of the protein is used as the antigen to induce antibody formation. A synthetic peptide, when coupled to a large protein carrier, can induce an animal to produce antibodies that bind to that part (the epitope) of the full-size, natural protein. Biosynthetically or chemically attaching the epitope to an unrelated protein is called *epitope tagging*. As we'll see throughout this book, antibodies generated using either peptide epitopes or intact proteins are extremely versatile reagents for isolating, detecting, and characterizing proteins.

Detecting Proteins in Gels Proteins embedded within a one- or two-dimensional gel usually are not visible. The two general approaches for detecting proteins in gels are either to label or stain the proteins while they are still within the gel or to electrophoretically transfer the proteins to a membrane made of nitrocellulose or polyvinylidene difluoride and then detect them. Proteins within gels are usually stained with an organic dye or a silver-based stain, both detected with normal visible light, or with a fluorescent dye that requires specialized detection equipment. Coomassie blue is the most commonly used organic dye, typically used to detect ~1000 ng of

protein, with a lower limit of detection of ~4–10 ng. Silver staining or fluorescence staining are more sensitive (lower limit of ~1 ng). Coomassie and other stains can also be used to visualize proteins after transfer to membranes; however, the most common method to visualize proteins in these membranes is immunoblotting, also called Western blotting.

Immunoblotting combines the resolving power of gel electrophoresis and the specificity of antibodies. This multi-step procedure is commonly used to separate proteins and then identify a specific protein of interest. As shown in Figure 3-39, two different antibodies are used in this method, one that is specific for the desired protein and a second that binds to the first and is linked to an enzyme or other molecule that permits detection of the first antibody (and thus the protein of interest to which it binds). Enzymes to which the second antibody is attached can either generate a visible colored product or, by a process called *chemiluminescence*, produce light that can readily be recorded by film or a sensitive detector. The two different antibodies, sometimes called a “sandwich,” are used to amplify the signals and improve sensitivity. If an antibody is not available but the gene encoding the protein is available and can be used to express the protein, recombinant DNA methods (see Chapter 5) can incorporate a small peptide epitope (epitope tagging) into the normal sequence of the protein that can be detected by a commercially available antibody to that epitope.

Radioisotopes Are Indispensable Tools for Detecting Biological Molecules

A sensitive method for tracking a protein or other biological molecule is by detecting the radioactivity emitted from radioisotopes introduced into the molecule. At least one atom in a radiolabeled molecule is present in a radioactive form, called a **radioisotope**.

Radioisotopes Useful in Biological Research Hundreds of biological molecules (e.g., amino acids, nucleosides, and numerous metabolic intermediates) labeled with various radioisotopes are commercially available. These preparations vary considerably in their *specific activity*, which is the amount of radioactivity per unit of material, measured in disintegrations per minute (dpm) per millimole. The specific activity of a labeled compound depends on the probability of decay of the radioisotope, determined by its *half-life*, which is the time required for half the atoms to undergo radioactive decay. In general, the shorter the half-life of a radioisotope, the higher its specific activity (Table 3-1).

The specific activity of a labeled compound must be high enough that sufficient radioactivity is incorporated into molecules to be accurately detected. For example, methionine and cysteine labeled with sulfur-35 (^{35}S) are widely used to biosynthetically label cellular proteins because preparations of these amino acids with high specific activities ($>10^{15}$ dpm/mmol) are available. Likewise, commercial preparations of ^3H -labeled nucleic acid precursors have much higher specific activities than those of the corresponding ^{14}C -labeled preparations. In most experiments, the former are preferable

EXPERIMENTAL FIGURE 3-39 Western blotting (immunoblotting) combines several techniques to resolve and detect a specific protein. Step **1**: After a protein mixture has been electrophoresed through an SDS gel, the separated bands (or spots, for a two-dimensional gel) are transferred (blotted) from the gel onto a porous membrane from which it is not readily removed. Step **2**: The membrane is flooded with a solution of antibody (Ab_1) specific for the desired protein and allowed to incubate for a while. Only the membrane-bound band containing this protein binds the antibody, forming a layer of antibody molecules (whose position cannot be seen at this point). Then the

membrane is washed to remove unbound Ab_1 . Step **3**: The membrane is incubated with a second antibody (Ab_2) that specifically recognizes and binds to the first Ab_1 . This second antibody is covalently linked to either an enzyme (e.g., alkaline phosphatase, which can catalyze a chromogenic reaction), a radioactive isotope, or some other substance whose presence can be detected with great sensitivity. Step **4**: Finally, the location and amount of bound Ab_2 are detected (e.g., by a deep-purple precipitate from chromogenic reaction), permitting the electrophoretic mobility (and therefore the mass) of the desired protein to be determined, as well as its quantity (based on band intensity).

because they allow RNA or DNA to be adequately labeled after a shorter time of incorporation or require a smaller cell sample. Various phosphate-containing compounds in which the phosphorus atom is the radioisotope phosphorus-32 are readily available. Because of their high specific activity, ^{32}P -labeled nucleotides are routinely used to label nucleic acids in cell-free systems.

Labeled compounds in which a radioisotope replaces atoms normally present in the molecule have virtually the same chemical properties as the corresponding nonlabeled compounds. Enzymes, for instance, generally cannot distinguish between substrates labeled in this way and their nonla-

beled substrates. The presence of such radioactive atoms is indicated with the isotope in brackets (no hyphen) as a prefix (e.g., [3H]leucine). In contrast, labeling almost all biomolecules (e.g., protein or nucleic acid) with the radioisotope iodine-125 (^{125}I) requires the covalent addition of ^{125}I to a molecule that normally does not have iodine as part of its structure. Because this labeling procedure modifies the chemical structure, the biological activity of the labeled molecule may differ somewhat from that of the nonlabeled form. The presence of such radioactive atoms is indicated with the isotope as a prefix with a hyphen (no bracket) (e.g., ^{125}I -trypsin). Standard methods for labeling proteins with ^{125}I result in covalent attachment of the ^{125}I primarily to the aromatic rings of tyrosine side chains (mono- and diiodotyrosine). Nonradioactive isotopes find increasing use in cell biology, especially in nuclear magnetic resonance studies and in mass spectroscopy applications, as will be explained below.

TABLE 3-1 Radioisotopes Commonly Used in Biological Research

Isotope	Half-Life
Phosphorus-32	14.3 days
Iodine-125	60.4 days
Sulfur-35	87.5 days
Tritium (hydrogen-3)	12.4 years
Carbon-14	5730.4 years

Labeling Experiments and Detection of Radiolabeled Molecules Whether labeled compounds are detected by autoradiography, a semiquantitative visual assay, or their radioactivity is measured in an appropriate “counter,” a highly quantitative assay that can determine the amount of a radiolabeled compound in a sample, depends on the nature of the experiment. In some experiments, both types of detection are used.

In one use of autoradiography, a tissue, cell, or cell constituent is labeled with a radioactive molecule, unassociated

radioactive material is washed away, and the structure of the sample is stabilized either by chemically cross-linking the macromolecules in the sample ("fixation") or by freezing it. The sample is then overlaid with a photographic emulsion sensitive to radiation. Development of the emulsion yields small silver grains whose distribution corresponds to that of the radioactive material and is usually detected by microscopy. Autoradiographic studies of whole cells were crucial in determining the intracellular sites where various macromolecules are synthesized and the subsequent movements of these macromolecules within cells. Various techniques employing fluorescent microscopy, which we describe in Chapter 9, have largely supplanted autoradiography for studies of this type. However, autoradiography is sometimes used in various assays for detecting specific isolated DNA or RNA sequences at specific tissue locations (see Chapter 5) in a technique referred to as *in situ* hybridization.

Quantitative measurements of the amount of radioactivity in a labeled material are performed with several different instruments. A Geiger counter measures ions produced in a gas by the β particles or γ rays emitted from a radioisotope. These instruments are mostly handheld devices used to monitor radioactivity in the laboratory to protect investigators from excess exposure. In a scintillation counter, a radiolabeled sample is mixed with a liquid containing a fluorescent compound that emits a flash of light when it absorbs the energy of the β particles or γ rays released in the decay of the radioisotope; a phototube in the instrument detects and counts these light flashes. Phosphorimagers are used to detect radioactivity using a two-dimensional array detector, storing digital data on the number of decays in disintegrations per minute per small pixel of surface area. These instruments, which can be thought of as a kind of reusable electronic film, are commonly used to quantitate radioactive molecules separated by gel electrophoresis and are replacing photographic emulsions for this purpose.

A combination of labeling and biochemical techniques and of visual and quantitative detection methods is often employed in labeling experiments. For instance, to identify the major proteins synthesized by a particular cell type, a sample of the cells is incubated with a radioactive amino acid (e.g., [^{35}S]methionine) for a few minutes, during which time the labeled amino acid enters the cells and mixes with the cellular pool of unlabeled amino acids and some of the labeled amino acid is biosynthetically incorporated into newly synthesized protein. Subsequently unincorporated radioactive amino acid is washed away from the cells. The cells are harvested; the mixture of cellular proteins is extracted from the cells (for example, by a detergent solution) and then separated by any of the commonly used methods to resolve complex protein mixtures into individual components. Gel electrophoresis in combination with autoradiography or phosphorimager analysis is often the method of choice. The radioactive bands in the gel correspond to newly synthesized proteins, which have incorporated the radiolabeled amino acid. To detect a specific protein of interest rather than the entire ensemble of biosynthetically radiolabeled proteins, a

specific antibody to the protein of interest can be used to precipitate the protein away from the other proteins in the sample (immunoprecipitation). The precipitate is then solubilized under denaturing conditions, for example, in an SDS-containing buffer, to separate the antibody from the protein, and the sample is analyzed by SDS-PAGE followed by autoradiography. In this type of experiment, a fluorescent compound that is activated by the radiation ("scintillator") may be infused into the gel on completion of the electrophoretic separation so that the light emitted can be used to detect the presence of the labeled protein, either using film or a two-dimensional electronic detector. This method is particularly useful for weak β emitters such as ^3H .

Pulse-chase experiments are particularly useful for tracing changes in the intracellular location of proteins or the modification of a protein or metabolite over time. In this experimental protocol, a cell sample is exposed to a radiolabeled compound that can be incorporated or otherwise attached to a cellular molecule of interest—the "pulse"—for a brief period. The pulse ends when the unincorporated radioactive molecules are washed away and the cells are exposed to a vast excess of the identical, but unlabeled compound to dilute the radioactivity of any remaining, but unincorporated radioactive compound. This procedure prevents further incorporation of significant amounts of radiolabel after the "pulse" period and initiates the "chase" period (Figure 3-40). Samples taken periodically during the chase period are assayed to determine the location or chemical form of the radiolabel as a function of time. Often, pulse-chase experiments, in which the protein is detected by autoradiography after immunoprecipitation and SDS-PAGE, are used to follow the rate of synthesis, modification, and degradation of proteins by adding radioactive amino acid precursors during the pulse and then detecting the amounts and characteristics of the radioactive protein during the chase. One can thus observe postsynthetic modifications of the protein that change its electrophoretic mobility and the rate of degradation of a specific protein, which is detected as the loss of signal with increasing time of chase. A classic use of the pulse-chase technique was in studies to elucidate the pathway traversed by secreted proteins from their site of synthesis in the endoplasmic reticulum to the cell surface (see Chapter 14).

Mass Spectrometry Can Determine the Mass and Sequence of Proteins

Mass spectrometry (MS) is a powerful technique for characterizing proteins, especially for determining the mass of a protein or fragments of a protein. With such information in hand, it is also possible to determine part of or all of the protein's sequence. This method permits the very highly accurate direct determination of the ratio of the mass (m) of a charged molecule (molecular ion) to its charge (z), or m/z . Techniques are then used to deduce the absolute mass of the molecular ion. There are four key features of all mass spectrometers. The first is an ion source, from which charge, usually in the form of protons, is transferred to the peptide or

EXPERIMENTAL FIGURE 3-40 Pulse-chase experiments can track the pathway of protein modification or movement within cells. (a) To follow the fate of a specific newly synthesized protein in a cell, cells were incubated with [³⁵S]methionine for 0.5 h (the pulse) to label all newly synthesized proteins, and the radioactive amino acid not incorporated into the cells was then washed away. The cells were further incubated (the chase) for varying times up to 24 hours, and samples from each time of chase were subjected to immunoprecipitation to isolate one specific protein (here the low-density lipoprotein receptor). SDS-PAGE of the immunoprecipitates followed by autoradiography permitted visualization of the one specific protein, which is initially synthesized as a small precursor (*p*) and then rapidly modified to a larger mature form (*m*) by addition of carbohydrates. About half of the labeled protein was converted from *p* to *m* during the pulse; the rest was converted after 0.5 hour of chase. The protein remains stable for 6–8 hours before it begins to be degraded (indicated by reduced band intensity). (b) The same experiment was performed in cells in which a mutant form of the protein is made. The mutant *p* form cannot be properly converted to the *m* form, and it is more quickly degraded than the normal protein. [Adapted from K. F. Kozarsky, H. A. Brush, and M. Krieger, 1986, *J. Cell Biol.* **102**(5):1567–1575.]

protein molecules. The formation of these ions occurs in the presence of a high electric field that then directs the charged molecular ions into the second key component, the mass analyzer. The mass analyzer, which is always in a high vacuum chamber, physically separates the ions on the basis of their differing mass-to-charge (m/z) ratios. The mass-separated ions are subsequently directed to strike a detector, the third key component, which provides a measure of the relative abundances of each of the ions in the sample. The fourth essential component is a computerized data system that is used to calibrate the instrument; acquire, store, and process the resulting data; and often direct the instrument automatically to collect additional specific types of data from the sample, based on the initial observations. This type of automated feedback is used for the tandem MS (MS/MS) peptide-sequencing methods described below.

The two most frequently used methods of generating ions of proteins and protein fragments are (1) matrix-assisted laser desorption/ionization (MALDI) and (2) electrospray

EXPERIMENTAL FIGURE 3-41 Molecular mass can be determined by matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry. In a MALDI-TOF mass spectrometer, pulses of light from a laser ionize a protein or peptide mixture that is absorbed on a metal target (step 1). An electric field accelerates the ions in the sample toward the detector (steps 2 and 3). The time to the detector is proportional to the square root of the mass-to-charge (m/z) ratio. For ions having the same charge, the smaller ions move faster (shorter time to the detector). The molecular weight is calculated using the time of flight of a standard.

(ES). In MALDI (Figure 3-41) the peptide or protein sample is mixed with a low-molecular-weight, UV-absorbing organic acid (the matrix) and then dried on a metal target. Energy from a laser ionizes and vaporizes the sample, producing singly charged molecular ions from the constituent molecules. In ES (Figure 3-42a), the sample of peptides or proteins in solution is converted into a fine mist of tiny droplets by spraying through a narrow capillary at atmospheric pressure. The droplets are formed in the presence of a high electric field, rendering them highly charged. The droplets evaporate in their short flight (mm) to the entrance of the mass spectrometer's analyzer, forming multiply charged ions from the peptides and proteins. The gaseous ions are sampled into the analyzer region of the MS, where they are then accelerated by electric fields and separated by the mass analyzer on the basis of their m/z .

The two most frequently used mass analyzers are time-of-flight (TOF) instruments and ion traps. TOF instruments exploit the fact that the time it takes an ion to pass through the length of the analyzer before reaching the detector is proportional to the square root of m/z (smaller ions move faster than larger ones with the same charge; see Figure 3-41). In ion-trap analyzers, tunable electric fields are used to capture, or "trap," ions with a specific m/z and to sequentially pass the trapped ions out of the analyzer onto the detector (see Figure 3-42a). By varying the electric fields, ions with a wide range of m/z values can be examined one by one, producing a mass spectrum, which is a graph of m/z (x axis) versus relative abundance (y axis) (Figure 3-42b, top panel).

EXPERIMENTAL FIGURE 3-42 Molecular mass of proteins and peptides can be determined by electrospray ionization ion-trap mass spectrometry. (a) Electrospray (ES) ionization converts proteins and peptides in a solution into highly charged gaseous ions by passing the solution through a needle (forming the droplets) that has a high voltage across it (charging the droplets). Evaporation of the solvent produces gaseous ions that enter a mass spectrometer. The ions are analyzed by an ion-trap mass analyzer that then directs ions to the detector. (b) *Top panel:* Mass spectrum of a mixture of three major and several minor peptides is presented as the relative abundance of the ions striking the detector (y axis) as a function of the mass-to-charge (m/z) ratio (x axis). *Bottom panel:* In an MS/MS instrument such as the ion trap shown in part (a), a specific peptide ion can be selected for

fragmentation into smaller ions that are then analyzed and detected. The MS/MS spectrum (also called the product-ion spectrum) provides detailed structural information about the parent ion, including sequence information for peptides. Here the ion with an m/z of 836.47 was selected and fragmented and the m/z mass spectrum of the product ions measured. Note there is no longer an ion with an m/z of 836.47 present because it was fragmented. From the varying sizes of the product ions, the understanding that peptide bonds are often broken in such experiments, the known m/z values for individual amino acid fragments, and database information, the sequence of the peptide, FIIVGYVDDTQFVR, can be deduced. [Part (a) based on a figure from S. Carr; part (b), unpublished data from S. Carr.]

In tandem, or MS/MS, instruments, any given parent ion in the original mass spectrum (Figure 3-42b, *top panel*) can be mass-selected, broken into smaller ions by collision with an inert gas, and then the m/z and relative abundances of the resulting fragment ions measured (Figure 3-42b, *bottom panel*), all within the same machine in about 0.1 s per selected parent ion. This second round of fragmentation and analysis permits the sequences of short peptides (<25 amino acids) to be determined because collisional fragmentation occurs primarily at peptide bonds, so the differences in masses between ions correspond to the in-chain masses of the individual amino acids, permitting deduction of the sequence in conjunction with database sequence information (Figure 3-42b, *bottom panel*).

Mass spectrometry is highly sensitive, able to detect as little as 1×10^{-16} mol (100 attomoles) of a peptide or 10×10^{-15} mol (10 femtomoles) of a protein of 200,000 MW. Errors in mass measurement accuracy are dependent on the specific mass analyzer used but are typically ~0.01 percent for peptides and 0.05–0.1 percent for proteins. As described in Section 3.6, below, it is possible to use MS to analyze complex mixtures of proteins as well as purified proteins. Most commonly, protein samples are digested by proteases, and the peptide digestion products are subjected to analysis. An especially powerful application of MS is to take a complex mixture of proteins from a biological specimen, digest it with trypsin or other proteases, partially separate the components using liquid chromatography (LC), and then transfer the solution flowing out of the chromatographic column directly into an ES tandem mass spectrometer. This technique, called *LC-MS/MS*, permits the nearly continuous analysis of a very complex mixture of proteins.

The abundances of ions determined by mass spectrometry in any given sample are relative, not absolute, values. Therefore, if one wants to use MS to compare the amounts of a particular protein in two different samples (e.g., from a normal versus a mutant organism), it is necessary to have an internal standard in the samples whose amounts do not differ between the two samples. One then determines the amounts of the protein of interest relative to that of the standard in each sample. This permits quantitatively accurate inter-sample comparisons of protein levels. An alternative approach involves simultaneously comparing the amounts of proteins from two different cell or tissue samples that are mixed together. To do this, investigators first incubate one of the samples with amino acids containing “heavy” isotope atoms. These are biosynthetically incorporated into all of the proteins of that sample. Proteins from the two samples are then mixed together and analyzed by mass spectrometry. Proteins and peptides derived from the “heavy” sample can be distinguished in the mass spectrometer from those from the other, “light,” sample because of their higher masses. Thus a direct comparison of the relative amounts of each protein in each sample can be made. When the samples are cells grown in the laboratory, the method is called *stable isotope labeling with amino acids in cell culture* (SILAC).

Protein Primary Structure Can Be Determined by Chemical Methods and from Gene Sequences

The classic method for determining the amino acid sequence of a protein is Edman degradation. In this procedure, the free amino group of the N-terminal amino acid of a polypeptide is labeled, and the labeled amino acid is then cleaved from the polypeptide and identified by high-pressure liquid chromatography. The polypeptide is left one residue shorter, with a new amino acid at the N-terminus. The cycle is repeated on the ever-shortening polypeptide until all the residues have been identified.

Before about 1985, biologists commonly used the Edman chemical procedure for determining protein sequences. Now, however, complete protein sequences usually are determined primarily by analysis of genome sequences. The complete genomes of several organisms have already been sequenced, and the database of genome sequences from humans and numerous model organisms is expanding rapidly. As discussed in Chapter 5, the sequences of proteins can be deduced from DNA sequences that are predicted to encode proteins.

A powerful approach for determining the primary structure of an isolated protein combines MS and the use of sequence databases. First, the peptide “mass fingerprint” of the protein is obtained by MS. A *peptide mass fingerprint* is the list of the molecular weights of peptides that are generated from the protein by digestion with a specific protease, such as trypsin. The molecular weights of the parent protein and its proteolytic fragments are then used to search genome databases for any similar-size protein with identical or similar peptide mass maps. Mass spectrometry can also be used to directly sequence peptides using MS/MS, as described above.

Protein Conformation Is Determined by Sophisticated Physical Methods

In this chapter, we have emphasized that protein function is dependent on protein structure. Thus, to figure out exactly how a protein works, its three-dimensional structure must be determined. Determining a protein’s conformation requires sophisticated physical methods and complex analyses of the experimental data. We briefly describe three methods used to generate three-dimensional models of proteins.

X-ray Crystallography The use of x-ray crystallography to determine the three-dimensional structures of proteins was pioneered by Max Perutz and John Kendrew in the 1950s. In this technique, beams of x-rays are passed through a protein crystal in which millions of protein molecules are precisely aligned with one another in a rigid crystalline array. The wavelengths of x-rays are about 0.1–0.2 nm, short enough to determine the positions of individual atoms in the protein. The electrons in the atoms of the crystal scatter the x-rays, which produce a diffraction pattern of discrete spots when they are intercepted by photographic film or an electronic detector (Figure 3-43). Such patterns are extremely complex—composed of as many as 25,000 diffraction spots, or reflections,

EXPERIMENTAL FIGURE 3-43 X-ray crystallography provides diffraction data from which the three-dimensional structure of a protein can be determined. (a) Basic components of an x-ray crystallographic determination. When a narrow beam of x-rays strikes a crystal, part of it passes straight through and the rest is scattered (diffracted) in various directions. The intensity of the diffracted waves, which form periodic arrangements of diffraction spots, is recorded on an x-ray film or with a solid-state electronic detector. (b) X-ray diffraction pattern for a protein crystal collected on a solid-state detector. From complex analyses of patterns of spots like this one, the location of the atoms in a protein can be determined. [Part (a) adapted from L. Stryer, 1995, *Biochemistry*, 4th ed., W. H. Freeman and Company, p. 64; part (b) courtesy of J. Berger.]

whose measured intensities vary depending on the distribution of the electrons, which is, in turn, determined by the atomic structure and three-dimensional conformation of the protein. Elaborate calculations and modifications of the protein (such as the binding of heavy metals) must be made to interpret the diffraction pattern and calculate the distribution

of electrons (called the *electron density map*). With the three-dimensional electron density map in hand, one then “fits” a molecular model of the protein to match the electron density, and it is these models that one sees in the various diagrams of proteins throughout this book (e.g., Figure 3-8). The process is analogous to reconstructing the precise shape of a rock from the ripples that it creates when thrown into a pond. Although sometimes the structures of parts of the protein cannot be clearly defined, using x-ray crystallography, researchers are systematically determining the structures of representative types of most proteins. To date, the detailed three-dimensional structures of more than 18,000 proteins have been established using x-ray crystallography. These structures can be found in the Research Collaboratory for Structural Bioinformatics Protein Data Bank (<http://www.rcsb.org/pdb/home/home.do>), each with its own PDB entry.

Cryoelectron Microscopy Although some proteins readily crystallize, obtaining crystals of others—particularly large multisubunit proteins and membrane-associated proteins—requires a time-consuming, often robot-assisted trial-and-error effort to find just the right conditions, if they can be found at all. (Growing crystals suitable for structural studies is as much an art as a science.) There are several ways to determine the structures of such difficult-to-crystallize proteins. One is cryoelectron microscopy. In this technique, a protein sample is rapidly frozen in liquid helium to preserve its structure and then examined in the frozen, hydrated state in a cryoelectron microscope. Pictures of the protein are taken at various angles and recorded on film using a low dose of electrons to prevent radiation-induced damage to the structure. Sophisticated computer programs analyze the images and reconstruct the protein’s structure in three dimensions. Recent advances in cryoelectron microscopy permit researchers to generate molecular models that can help provide insight into how the protein functions. The use of cryoelectron microscopy and other types of electron microscopy for visualizing cell structures is discussed in Chapter 9.

NMR Spectroscopy The three-dimensional structures of small proteins containing as many as 200 amino acids can be studied routinely with nuclear magnetic resonance (NMR) spectroscopy. Specialized approaches can be used to extend the size range to somewhat larger proteins. In this technique, a concentrated protein solution is placed in a magnetic field, and the effects of different radio frequencies on the nuclear spin states of different atoms are measured. The spin state of any atom is influenced by neighboring atoms in adjacent residues, with closely spaced residues having a greater influence than distant residues. From the magnitude of the effect, the distances between residues can be calculated by a triangulation-like process; these distances are then used to generate a model of the three-dimensional structure of the protein. An important distinction between x-ray crystallography and NMR spectroscopy is that the former method directly determines the locations of the atoms while the latter directly determines the distances between the atoms.

Although NMR does not require the crystallization of a protein, a definite advantage, this technique is limited to proteins smaller than about 20 kDa. However, NMR analysis can provide information about the ability of a protein to adopt a set of closely related, but not exactly identical, conformations and to move between these conformations (protein dynamics). This is a common feature of proteins, which are not absolutely rigid structures but can “breathe” or exhibit slight variations in the relative positions of their constituent atoms. In some cases these variations can have functional significance, for example in how proteins bind to one another. NMR structural analysis has been particularly useful in studying isolated protein domains, which can often be obtained as stable structures and tend to be small enough for this technique. To date, there are more than 5000 NMR-determined protein structures available in the Protein Data Bank (<http://www.rcsb.org/pdb/home/home.do>).

KEY CONCEPTS of Section 3.5

Purifying, Detecting, and Characterizing Proteins

- Proteins can be separated from other cell components and from one another on the basis of differences in their physical and chemical properties.
- Various assays are used to detect and quantify proteins. Some assays use a light-producing reaction to generate a readily detected signal. Other assays produce an amplified colored signal with enzymes and chromogenic substrates.
- Centrifugation separates proteins on the basis of their rates of sedimentation, which are influenced by their masses and shapes (see Figure 3-35).
- Electrophoresis separates proteins on the basis of their rates of movement in an applied electric field. SDS-polyacrylamide gel electrophoresis (SDS-PAGE) can resolve polypeptide chains differing in molecular weight by 10 percent or less (see Figure 3-36). Two-dimensional gel electrophoresis provides additional resolution by separating proteins first by charge (first dimension) and then by mass (second dimension).
- Liquid chromatography separates proteins on the basis of their rates of movement through a column packed with spherical beads. Proteins differing in mass are resolved on gel filtration columns; those differing in charge, on ion-exchange columns; and those differing in ligand-binding properties, on affinity columns, including antibody-based affinity chromatography (see Figure 3-38).
- Antibodies are powerful reagents used to detect, quantify, and isolate proteins.
- Immunoblotting, also called *Western blotting*, is a frequently used method to study specific proteins that exploits the high specificity and sensitivity of protein detection by antibodies and the high-resolution separation of proteins by SDS-PAGE (see Figure 3-39).

- Isotopes, both radioactive and “heavy” or “light” nonradioactive, play a key role in the study of proteins and other biomolecules. They can be incorporated into molecules without changing the chemical composition of the molecule or as add-on tags. They can be used to help detect the synthesis, location, processing, and stability of proteins.
- Autoradiography is a semiquantitative technique for detecting radioactively labeled molecules in cells, tissues, or electrophoretic gels.
- Pulse-chase labeling can determine the intracellular fate of proteins and other metabolites (see Figure 3-40).
- Mass spectrometry is a very sensitive and highly precise method of detecting, identifying, and characterizing proteins and peptides.
- Three-dimensional structures of proteins are obtained by x-ray crystallography, cryoelectron microscopy, and NMR spectroscopy. X-ray crystallography provides the most detailed structures but requires protein crystallization. Cryoelectron microscopy is most useful for large protein complexes, which are difficult to crystallize. Only relatively small proteins are amenable to NMR analysis.

3.6 Proteomics

For most of the twentieth century, the study of proteins was restricted primarily to the analysis of individual proteins. For example, one would study an enzyme by determining its enzymatic activity (substrates, products, rate of reaction, requirement for cofactors, pH, etc.), its structure, and its mechanism of action. In some cases, the relationships between a few enzymes that participate in a metabolic pathway might also be studied. On a broader scale, the localization and activity of an enzyme would be examined in the context of a cell or tissue. The effects of mutations, diseases, or drugs on the expression and activity of the enzyme might also be the subject of investigation. This multipronged approach provided deep insight into the function and mechanisms of action of individual proteins or relatively small numbers of interacting proteins. However, such a one-by-one approach to studying proteins does not readily provide a global picture of what is happening in the proteome of a cell, tissue, or entire organism.

Proteomics Is the Study of All or a Large Subset of Proteins in a Biological System

The advent of genomics (sequencing of genomic DNA and its associated technologies, such as simultaneous analysis of the levels of all mRNAs in cells and tissues) clearly showed that a global, or systems, approach to biology could provide unique and highly valuable insights. Many scientists recognized that a global analysis of the proteins in biological systems had the potential for equally valuable contributions to our understanding. Thus a new field was born—**proteomics**.

EXPERIMENTAL FIGURE 3-44 LC-MS/MS is used to identify the proteins in a complex biological sample. A complex mixture of proteins in a biological sample (e.g., isolated preparation of Golgi organelles) is digested with a protease; the mixture of resulting peptides is fractionated by liquid chromatography (LC) into multiple, less complex, fractions, which are slowly but continuously injected by

electrospray ionization into a tandem mass spectrometer. The fractions are then sequentially subjected to multiple cycles of MS/MS until masses and sequences of many of the peptides are determined and used to identify the proteins in the original biological sample through comparison with protein databases. [Based on a figure provided by S. Carr.]

Proteomics is the systematic study of the amounts, modifications, interactions, localization, and functions of all or subsets of proteins at the whole-organism, tissue, cellular, and subcellular levels.

A number of broad questions are addressed in proteomic studies:

- In a given sample (whole organism, tissue, cell, subcellular compartment), what fraction of the whole proteome is expressed (i.e., which proteins are present)?
- Of those proteins present in the sample, what are their relative abundances?
- What are the relative amounts of the different splice forms and chemically modified forms (e.g., phosphorylated, methylated, fatty acylated) of the proteins?

- Which proteins are present in large multiprotein complexes, and which proteins are in each complex? What are the functions of these complexes, and how do they interact?
- When the state (e.g., growth rate, stage of cell cycle, differentiation, stress level) of a cell changes, do the proteins in the cell or secreted from the cell change in a characteristic (*fingerprint-like*) fashion? Which proteins change and how (relative amounts, modifications, splice forms, etc.)? (This is a form of *protein expression profiling* that complements the *transcriptional (mRNA) profiling* discussed in Chapter 7.)
- Can such fingerprint-like changes be used for diagnostic purposes? For example, do certain cancers or heart disease cause characteristic changes in blood proteins? Can the proteomic fingerprint help determine if a given cancer is resistant or sensitive to a particular chemotherapeutic drug? Proteomic

EXPERIMENTAL FIGURE 3-45 Density-gradient centrifugation and LC-MS/MS can be used to identify many of the proteins in organelles.

(a) The cells in liver tissue were mechanically broken to release the organelles, and the organelles were partially separated by density-gradient centrifugation. The locations of the organelles—which were spread out through the gradient and somewhat overlapped with one another—were determined using immunoblotting with antibodies that recognize previously identified, organelle-specific proteins. Fractions from the gradient were subjected to proteolysis and LC-MS/MS to identify the peptides, and hence the proteins, in each fraction. Comparisons with the locations of the organelles in the gradient (called protein correlation profiling) permitted assignment of many individual proteins to one or more organelles (organelle proteome identification). (b) The hierarchical breakdown of data derived from the procedures in part (a). Note that not all proteins identified could be assigned to organelles and some proteins were assigned to more than one organelle. [From L. J. Foster et al., 2006, *Cell* 125(1):187–199.]

fingerprints can also be the starting point for studies of the mechanisms underlying the change of state. Proteins (and other biomolecules) that show changes that are diagnostic of a particular state are called *biomarkers*.

- Can changes in the proteome help define targets for drugs or suggest mechanisms by which that drug might induce toxic side effects? If so, it might be possible to engineer modified versions of the drug with fewer side effects.

These are just a few of the questions that can be addressed using proteomics. The methods used to answer these questions are as diverse as the questions themselves, and their numbers are growing rapidly.

Advanced Techniques in Mass Spectrometry Are Critical to Proteomic Analysis

Advances in proteomics technologies (e.g., mass spectrometry) profoundly affect the types of questions that can be practically studied. For many years, two-dimensional gel electrophoresis has allowed researchers to separate, display, and characterize a complex mixture of proteins (see Figure 3-37). The spots on a two-dimensional gel can be excised, the protein fragmented by proteolysis (e.g., by trypsin digestion), and the fragments identified by MS. An alternative to this two-dimensional gel method is *high-throughput LC-MS/MS*. Figure 3-44 outlines the general LC-MS/MS approach, in which a complex mixture of proteins is digested with a protease; the myriad resulting peptides are fractionated by LC into multiple, less complex fractions, which are slowly but continuously injected by electrospray ionization into a tandem mass spectrometer. The fractions are then sequentially subjected to multiple cycles of MS/MS until sequences of many of the peptides are determined and used to identify from databases the proteins in the original biological sample.

An example of the use of LC-MS/MS to identify many of the proteins in each organelle is seen in Figure 3-45. Cells from murine (mouse) liver tissue were mechanically broken to

release the organelles, and the organelles were partially separated by density-gradient centrifugation. The locations of the organelles in the gradient were determined using immunoblotting with antibodies that recognize previously identified, organelle-specific proteins. Fractions from the gradient were

subjected to LC-MS/MS to identify the proteins in each fraction, and the distributions in the gradient of many individual proteins were compared with the distributions of the organelles. This permitted assignment of many individual proteins to one or more organelles (organelle proteome proteome profiling). More recently, a combination of organelle purification, MS, biochemical localization and computational methods has been used to show that at least 1000 distinct proteins are localized in the mitochondria of humans and mice.

Proteomics combined with molecular genetics methods are currently being used to identify all protein complexes in a eukaryotic cell, the yeast *Saccharomyces cerevisiae*. Approximately 500 complexes have been identified, with an average of 4.9 distinct proteins per complex, and these in turn are involved in at least 400 complex-to-complex interactions. Such systematic proteomic studies are providing new insights into the organization of proteins within cells and how proteins work together to permit cells to live and function.

KEY CONCEPTS of Section 3.6

Proteomics

- Proteomics is the systematic study of the amounts (and changes in the amounts), modifications, interactions, localization, and functions of all or subsets of all proteins in biological systems at the whole-organism, tissue, cellular, and subcellular levels.
- Proteomics provides insights into the fundamental organization of proteins within cells and how this organization is influenced by the state of the cells (e.g., differentiation into distinct cell types; response to stress, disease, and drugs).
- A wide variety of methods are used for proteomic analyses, including two-dimensional gel electrophoresis, density-gradient centrifugation, and mass spectroscopy (MALDI-TOF and LC-MS/MS).
- Proteomics has helped begin to identify the proteomes of organelles ("organelle proteome profiling") and the organization of individual proteins into multiprotein complexes that interact in a complex network to support life and cellular function (see Figure 3-45).

Perspectives for the Future

Impressive expansion of the computational power of computers is at the core of advances in determining the three-dimensional structures of proteins. For example, vacuum tube computers running on programs punched on cards were used to solve the first protein structures on the basis of x-ray crystallography, a process that at the time took years but can now be accomplished in a matter of days and in some cases hours. In the future, researchers aim to predict the structures of proteins using only amino acid sequences deduced from gene sequences. This computationally chal-

lenging problem requires supercomputers or large clusters of computers working in synchrony. Currently, only the structures of very small domains containing 100 residues or fewer can be predicted at a low resolution. However, continued developments in computing and models of protein folding, combined with large-scale efforts to solve the structures of all protein structural motifs by x-ray crystallography, will allow the prediction of the structures of larger proteins. With an exponentially expanding database of structurally defined motifs, domains, and proteins, scientists will be able to identify the motifs in an unknown protein, match the motif to the sequence, and use this to predict the three-dimensional structure of the entire protein.

New combined approaches will also help in determining high-resolution structures of molecular machines. Although these very large macromolecular assemblies usually are difficult to crystallize and thus to solve by x-ray crystallography, they can be imaged in a cryoelectron microscope at liquid helium temperatures and high electron energies. From millions of individual "particles," each representing a random view of the protein complex, the three-dimensional structure can be built. Because subunits of the complex may already be solved by crystallography, a composite structure consisting of the x-ray-derived subunit structures fit to the EM-derived model will be generated.

Methods for rapid structure determination combined with identification of novel substrates and inhibitors will help determine the structures of enzyme-substrate complexes and transition states and thus help provide detailed information regarding the mechanisms of enzyme catalysis. Membrane proteins, because of the specialized environment in which they reside and their solubility characteristics, remain challenging, although progress in this area is accelerating.

Although our understanding of chaperone structure and activity continues to grow exponentially, a number of critical questions remain a mystery. We do not understand precisely how cells make the distinction between unfolded and misfolded versus properly folded. Clearly, the exposure of hydrophobic side chains plays a role, but what are the other determinants of this key recognition process? How is the decision made to turn from trying to refold a protein to degrading it?

The rapid development of new technologies can be expected to help solve some of the still outstanding problems in proteomics. It is becoming possible to identify and characterize intact proteins as large as 30–70 kDa in complex mixtures using MS techniques without first digesting the samples into peptides—a method called the "top-down" approach, in contrast to starting with fragments of the protein ("bottom-up" approach). An ongoing problem in proteomic analysis of complex mixtures is that it is difficult to detect and identify protein fragments from samples whose concentrations in the sample differ by more than 1000-fold: some samples, such as blood plasma, contain proteins whose concentrations vary over a 10^{11} -fold range. Routine analysis of specimens with such diverse concentrations should dramatically improve the mechanistic and diagnostic value of blood plasma proteomics.

Review the Concepts

1. The three-dimensional structure of a protein is determined by its primary, secondary, and tertiary structures. Define the *primary*, *secondary*, and *tertiary structures*. What are some of the common secondary structures? What are the forces that hold together the secondary and tertiary structures?
2. Proper folding of proteins is essential for their biological activity. In general, the functional conformation of a protein is the conformation with lowest energy. This means that if an unfolded protein is allowed to reach equilibrium, it should assemble automatically into its native, functioning folded state. Why then is there a need for molecular chaperones and chaperonins in cells? What different roles do molecular chaperones and chaperonins play in the folding of proteins?
3. Enzymes catalyze chemical reactions. What constitutes the active site of an enzyme? What are the turnover number (k_{cat}), the Michaelis constant (K_m), and the maximal velocity ($V_{\max}$) of an enzyme? The k_{cat} for carbonic anhydrase is 5×10^5 molecules/s. This is a “rate constant” but not a “rate.” What is the difference? By what concentration would you multiply this rate constant in order to determine an actual rate of product formation (V)? Under what circumstances would this rate become equal to the maximal velocity ($V_{\max}$) of the enzyme?
4. The following reaction coordinate diagram charts the energy of a substrate molecule (S) as it passes through a transition state ($X^\ddagger$) on its way to becoming a stable product (P) alone or in the presence of one of two different enzymes (E1 and E2). How does the addition of either enzyme affect the change in Gibbs’s free energy (ΔG) for the reaction? Which of the two enzymes binds with greater affinity to the substrate?

Which enzyme better stabilizes the transition state? Which enzyme functions as a better catalyst?

5. A healthy adaptive immune system can raise antibodies that recognize and bind with high affinity to almost any stable molecule. The molecule to which an antibody binds is known as “antigen.” Antibodies have been exploited by enterprising scientists to generate valuable tools for research, diagnosis, and therapy. One clever application is the generation of antibodies that function like enzymes to catalyze complicated chemical reactions. If you wished to produce such a “catalytic” antibody, what would you suggest using as the antigen? Should it be the substrate of the reaction? The product? Something else?
6. Proteins are degraded in cells. What is ubiquitin, and what role does it play in tagging proteins for degradation? What is the role of proteasomes in protein degradation? How might proteasome inhibitors serve as chemotherapeutic (cancer-treating) agents?
7. The function of proteins can be regulated in a number of ways. What is cooperativity, and how does it influence protein function? Describe how protein phosphorylation and proteolytic cleavage can modulate protein function.
8. A number of techniques can separate proteins on the basis of their differences in mass. Describe the use of two of these techniques, centrifugation and gel electrophoresis. The blood proteins transferrin (MW 76 kDa) and lysozyme (MW 15 kDa) can be separated by rate-zonal centrifugation or SDS-polyacrylamide gel electrophoresis. Which of the two proteins will sediment faster during centrifugation? Which will migrate faster during electrophoresis?
9. Chromatography is an analytical method used to separate proteins. Describe the principles for separating proteins by gel filtration, ion-exchange, and affinity chromatography.
10. Various methods have been developed for detecting proteins. Describe how radioisotopes and autoradiography can be used for labeling and detecting proteins. How does Western blotting detect proteins?
11. Physical methods are often used to determine protein conformation. Describe how x-ray crystallography, cryoelectron

microscopy, and NMR spectroscopy can be used to determine the shape of proteins. What are the advantages and disadvantages of each method? Which is better for small proteins? Large proteins? Huge macromolecular assemblies?

12. Mass spectrometry is a powerful tool in proteomics. What are the four key features of a mass spectrometer? Describe briefly how MALDI and two-dimensional polyacrylamide gel electrophoresis (2D-PAGE) could be used to identify a protein expressed in cancer cells but not in normal healthy cells.

Analyze the Data

1. Beautiful models of macromolecules such as proteins and nucleic acids are generated from files of atomic coordinates obtained usually from x-ray diffraction of crystallized samples or NMR analysis of the molecules in solution. The Protein Data Bank (PDB) is a publicly accessible repository of macromolecular atomic coordinate files that can be accessed online at <http://www.rcsb.org>. Access the PDB and familiarize yourself with its homepage. How many molecular structures does it contain today? What is the “Molecule of the Month”? Download a coordinate file for the serine protease chymotrypsin by typing the accession code “1ACB” into the search window. This will take you to a page describing the x-ray crystal structure of a complex between bovine alpha-chymotrypsin and the small pseudosubstrate inhibitor protein eglin-c. When and in what journal was the study reporting this structural model published? Click on the “Download File” link, select “PDB File (Text)”, and download the file “1ACB.pdb”. This is an atomic coordinate (.pdb) file that specifies the relative positions for each atom in this protein complex as determined experimentally by x-ray crystallography. Open the file in a text viewer or word processor and look at its format. The first several hundred lines contain background information including the names of the molecules, their natural sources, how they were prepared for the experiment, statistical analysis of the model quality, and bibliographic information. Eventually, you will arrive at a long list of lines that each begin with “ATOM”. These are the coordinates, listed by atom number, atom type, amino acid type, and chain number. Each “ATOM” line ends with five numbers representing the atomic position on an x, y, z axis, its “occupancy,” and its “thermal factor.” Close the file and download software for viewing the molecular model. There are many, such as RasMol, iMol, Swiss-PDB Viewer, and PyMol, that are available for download in a free format for educational purposes. Open the 1ACB.pdb file and twirl it around in the viewer. Can you identify the protease? The inhibitor protein? Can you find the enzyme’s active site? What other observations can you make about serine proteases from the model of this inactivated complex?

2. Proteomics involves the global analysis of protein expression. In one approach, all the proteins in control cells and treated cells are extracted and subsequently separated using two-dimensional gel electrophoresis. Typically, hundreds or thousands of protein spots are resolved and the steady-state levels of each protein are compared between

control and treated cells. In the following example, only a few protein spots are shown for simplicity. Proteins are separated in the first dimension on the basis of charge by isoelectric focusing (pH 4–10) and then separated by size by SDS-polyacrylamide gel electrophoresis. Proteins are detected with a stain such as Coomassie blue and assigned numbers for identification.

a. Cells are treated with a drug (“1 Drug”) or left untreated (“Control”), and then proteins are extracted and separated by two-dimensional gel electrophoresis. The stained gels are shown below. What do you conclude about the effect of the drug on the steady-state levels of proteins 1–7?

b. You suspect that the drug may be inducing a protein kinase and so repeat the experiment in part (a) in the presence of ^{32}P -labeled inorganic phosphate. In this experiment the two-dimensional gels are exposed to x-ray film to detect the presence of ^{32}P -labeled proteins. The x-ray films are shown below. What do you conclude from this experiment about the effect of the drug on proteins 1–7?

c. To determine the cellular localization of proteins 1–7, the cells from part (a) were separated into nuclear and cytoplasmic fractions by differential centrifugation. Two-dimensional gels were run, and the stained gels are shown below. What do you conclude about the cellular localization of proteins 1–7?

d. Summarize the overall properties of proteins 1–7, combining the data from parts (a), (b), and (c). Describe how you could determine the identity of any one of the proteins.

Colored transmission electron micrograph of one ribosomal RNA transcription unit from a *Xenopus* oocyte. Transcription proceeds from left to right, with nascent ribosomal ribonucleoprotein complexes (rRNPs) growing in length as each successive RNA polymerase I molecule moves along the DNA template at the center. In this preparation each rRNP is oriented either above or below the central strand of DNA being transcribed, so that the overall shape is similar to a feather. In the nucleolus of a living cell, the nascent rRNPs extend in all directions, like a bottle brush. [Professor Oscar L. Miller/Science Photo Library.]

The extraordinary versatility of proteins as molecular machines and switches, cellular catalysts, and components of cellular structures was described in Chapter 3. In this chapter we consider how proteins are made, as well as other cellular processes that are critical for the survival of an organism and its descendants. Our focus will be on the vital molecules known as **nucleic acids**, and how they ultimately are responsible for governing all cellular function. As introduced in Chapter 2, nucleic acids are linear polymers of four types of nucleotides (see Figures 2-13, 2-16, and 2-17). These macromolecules (1) contain in the precise sequence of their nucleotides the information for determining the amino acid sequence and hence the structure and function of all the proteins of a cell, (2) are critical functional components of the cellular macromolecular factories that select and align amino acids in the correct order as a polypeptide chain is being synthesized, (3) catalyze a number of fundamental chemical reactions in cells, including formation of peptide bonds between amino acids during protein synthesis, and (4) regulate the expression of genes.

Basic Molecular Genetic Mechanisms

Deoxyribonucleic acid (DNA) is an informational molecule that contains in the sequence of its nucleotides the information required to build all the proteins of an organism, and hence the cells and tissues of that organism. It is ideally suited to perform this function on a molecular level. Chemically, it is extraordinarily stable under most terrestrial conditions, as exemplified by the ability to recover DNA sequence from bones and tissues that are tens of thousands of years old. Because of this, and because of repair mechanisms that operate in living cells, the long polymers that make up a DNA molecule can be up to 10^9 nucleotides long. Virtually all the information required for the development of a fertilized human egg into an adult made of trillions of cells with specialized functions can be stored in the sequence of the four types of nucleotides that makes up the $\approx 3 \times 10^9$ base pairs in the human genome. Because of the principles of base pairing discussed in the following, the information is readily copied with an error rate of <1 in 10^9 nucleotides per generation. The exact replication of this information in any

species assures its genetic continuity from generation to generation and is critical to the normal development of an individual. DNA fulfills these functions so well that it is the vessel for genetic information in all forms of life known (excluding RNA viruses, which are limited to extremely short genomes because of the relative instability of RNA compared to DNA, as we will see). The discovery that virtually all forms of life use DNA to encode their genetic information, and also use nearly the identical genetic code, implies that all forms of life descended from a common ancestor based on the storage of information in nucleic acid sequence. This information is accessed and replicated by specific base pairing between nucleotides. The information stored in DNA is arranged in hereditary units, known as genes, that control identifiable traits of an organism. In the process of transcription, the information stored in DNA is copied into **ribonucleic acid (RNA)**, which has three distinct roles in protein synthesis.

Portions of the DNA nucleotide sequence are copied into **messenger RNA (mRNA)** molecules that direct the synthesis of a specific protein. The nucleotide sequence of an mRNA molecule contains information that specifies the correct order of amino acids during the synthesis of a protein. The remarkably accurate, stepwise assembly of amino acids into proteins occurs by **translation** of mRNA. In this process, the nucleotide sequence of an mRNA molecule is “read” by a second type of RNA called **transfer RNA (tRNA)** with the aid of a third type of RNA, **ribosomal RNA (rRNA)**, and their associated proteins. As the correct amino acids are brought into sequence by tRNAs, they are linked by peptide bonds to make proteins. RNA synthesis is called **transcription** because the nucleotide sequence “language” of DNA is precisely copied, or *transcribed*, into the nucleotide sequence of an RNA molecule. Protein synthesis is referred to as **translation** because the nucleotide sequence “language” of DNA and RNA is *translated* into the amino acid sequence “language” of proteins.

Discovery of the structure of DNA in 1953 and subsequent elucidation of how DNA directs synthesis of RNA, which then directs assembly of proteins—the so-called *central dogma*—were monumental achievements marking the early days of molecular biology. However, the simplified representation of the central dogma as DNA → RNA → protein does not reflect the role of proteins in the synthesis of nucleic acids. Moreover, as discussed here for bacteria and in later chapters for eukaryotes, proteins are largely responsible for *regulating gene expression*, the entire process whereby the information encoded in DNA is decoded into proteins in the correct cells at the correct times in development. As a consequence, hemoglobin is expressed only in cells in the bone marrow (reticulocytes) destined to develop into circulating red blood cells (erythrocytes), and developing neurons make the proper synapses (connections) with 10^{11} other developing neurons in the human brain. The fundamental molecular genetic processes of DNA replication, transcription, and translation must be carried out with extraordinary fidelity, speed, and accurate regulation for the

normal development of organisms as complex as prokaryotes and eukaryotes. This is achieved by chemical processes that operate with extraordinary accuracy coupled with multiple layers of checkpoint or surveillance mechanisms that test whether critical steps in these processes have occurred correctly before the next step is initiated. The highly regulated expression of genes necessary for the development of a multicellular organism requires integrating information from signals sent by distant cells in the developing organism, as well as from neighboring cells, and an intrinsic developmental program determined by earlier steps in embryogenesis taken by that cell’s progenitors. All of this regulation is dependent on control sequences in the DNA that function with proteins called *transcription factors* to coordinate the expression of every gene. RNA sequences we discuss in Chapter 8 that regulate RNA processing and translation also are encoded in DNA originally. Nucleic acids function as the “brains and central nervous system” of the cell, while proteins carry out the functions they specify.

In this chapter, we first review the structures and properties of DNA and RNA, and explore how the different characteristics of each type of nucleic acid make them suited for their respective functions in the cell. In the next several sections we discuss the basic processes summarized in Figure 4-1: transcription of DNA into RNA precursors, processing of these precursors to make functional RNA molecules, translation of mRNAs into proteins, and the replication of DNA. Proteins regulate cell structure and most of the biochemical reactions in cells, so we first consider how the amino acid sequences of proteins, which determines their three-dimensional structures and hence their functions, is encoded in DNA and translated. After outlining functions of mRNA, tRNA, and rRNA in protein synthesis, we present a detailed description of the components and biochemical steps in translation. Understanding these processes gives us a deep appreciation of the need to copy the nucleotide sequence of DNA precisely. Consequently, we next consider the molecular problems involved in DNA replication and the complex cellular machinery for ensuring accurate copying of the genetic material. Along the way, we compare these processes in prokaryotes and eukaryotes. The next section describes how damage to DNA is repaired, and how regions of different DNA molecules are exchanged in the process of **recombination** to generate new combinations of traits in the individual organisms of a species. The final section of the chapter presents basic information about viruses, parasites that exploit the cellular machinery for DNA replication, transcription, and protein synthesis. In addition to being significant pathogens, viruses are important model organisms for studying these cellular mechanisms of macromolecular synthesis and other cellular processes. Viruses have relatively simple structures compared to cells, and small genomes that made them tractable for historic early studies of these basic cellular processes. Viruses continue to teach important lessons in molecular cell biology today and have been adapted as experimental tools for introducing any desired genes into cells, tools that are currently being tested for their effectiveness in human gene therapy.

FIGURE 4-1 Overview of four basic molecular genetic processes.

In this chapter we cover the three processes that lead to production of proteins (1–3) and the process for replicating DNA (4). Because viruses utilize host-cell machinery, they have been important models for studying these processes. During transcription of a protein-coding gene by RNA polymerase (1), the four-base DNA code specifying the amino acid sequence of a protein is copied, or *transcribed*, into a precursor messenger RNA (pre-mRNA) by the polymerization of ribonucleoside triphosphate monomers (rNTPs). Removal of noncoding sequences and other modifications to the pre-mRNA (2), collectively known as *RNA processing*, produce a functional mRNA, which is transported to the

cytoplasm. During *translation* (3), the four-base code of the mRNA is decoded into the 20-amino acid language of proteins. Ribosomes, the macromolecular machines that translate the mRNA code, are composed of two subunits assembled in the nucleolus from ribosomal RNAs (rRNAs) and multiple proteins (left). After transport to the cytoplasm, ribosomal subunits associate with an mRNA and carry out protein synthesis with the help of transfer RNAs (tRNAs) and various translation factors. During DNA replication (4), which occurs only in cells preparing to divide, deoxyribonucleoside triphosphate monomers (dNTPs) are polymerized to yield two identical copies of each chromosomal DNA molecule. Each daughter cell receives one of the identical copies.

4.1 Structure of Nucleic Acids

DNA and RNA are chemically very similar. The primary structures of both are linear polymers composed of **monomers** called **nucleotides**. Both function primarily as informational molecules, carrying information in the exact sequence of their nucleotides. Cellular RNAs range in length from less than one hundred to many thousands of nucleotides. Cellular DNA molecules can be as long as several hundred million nucleotides. These large DNA units in association with proteins can be stained with dyes and visualized in the light microscope as chromosomes, so named because of their stainability. Though chemically similar, DNA and RNA exhibit some very important differences. For example, RNA can also function as a catalytic molecule. As we will see, it is the different and unique properties of DNA and RNA that makes them each suited for their specific roles in the cell.

A Nucleic Acid Strand Is a Linear Polymer with End-to-End Directionality

In all organisms, DNA and RNA are each comprised of only four different nucleotides. Recall from Chapter 2 that all nucleotides consist of an organic base linked to a five-carbon sugar that has a phosphate group attached to carbon 5. In RNA, the sugar is ribose; in DNA, deoxyribose (see Figure 2-16). The nucleotides used in synthesis of DNA and RNA contain five different bases. The bases *adenine* (A) and *guanine* (G) are **purines**, which contain a pair of fused rings; the bases *cytosine* (C), *thymine* (T), and *uracil* (U) are **pyrimidines**, which contain a single ring (see Figure 2-17). Three of these bases—A, G, and C—are found in both DNA and RNA; however, T is found only in DNA, and U only in RNA. (Note that the single-letter abbreviations for these bases are also commonly used to denote the entire nucleotides in nucleic acid polymers.)

FIGURE 4-2 Chemical directionality of a nucleic acid strand.

Shown here are alternative representations of a single strand of DNA containing only three bases: cytosine (C), adenine (A), and guanine (G). (a) The chemical structure shows a hydroxyl group at the 3' end and a phosphate group at the 5' end. Note also that two phosphoester bonds link adjacent nucleotides; this two-bond linkage commonly is referred to as a *phosphodiester bond*. (b) In the "stick" diagram (*top*), the sugars are indicated as vertical lines and the phosphodiester bonds as slanting lines; the bases are denoted by their single-letter abbreviations. In the simplest representation (*bottom*), only the bases are indicated. By convention, a polynucleotide sequence is always written in the 5'→3' direction (left to right) unless otherwise indicated.

A single nucleic acid strand has a *backbone* composed of repeating pentose-phosphate units from which the purine and pyrimidine bases extend as side groups. Like a polypeptide, a nucleic acid strand has an end-to-end chemical orientation: the *5' end* has a hydroxyl or phosphate group on the 5' carbon of its terminal sugar; the *3' end* usually has a hydroxyl group on the 3' carbon of its terminal sugar (Figure 4-2). This directionality, plus the fact that synthesis proceeds 5' to 3', has given rise to the convention that polynucleotide sequences are written and read in the 5'→3' direction (from left to right); for example, the sequence AUG is assumed to be (5')AUG(3'). As we will see, the 5'→3' directionality of a nucleic acid strand is an important property of the molecule. The chemical linkage between adjacent nucleotides, commonly called a *phosphodiester bond*, actually consists of two phosphoester bonds, one on the 5' side of the phosphate and another on the 3' side.

The linear sequence of nucleotides linked by phosphodiester bonds constitutes the primary structure of nucleic acids. Like polypeptides, polynucleotides can twist and fold into three-dimensional conformations stabilized by noncovalent bonds. Although the primary structures of DNA and RNA are generally similar, their three-dimensional conformations are quite different. These structural differences are critical to the different functions of the two types of nucleic acids.

Native DNA Is a Double Helix of Complementary Antiparallel Strands

The modern era of molecular biology began in 1953 when James D. Watson and Francis H. C. Crick proposed that DNA has a double-helical structure. Their proposal was based on analysis of x-ray diffraction patterns of DNA fibers generated by Rosalind Franklin and Maurice Wilkins, which showed that the structure was helical, and analyses of the base composition of DNA from multiple organisms by Erwin Chargaff and colleagues. Chargaff's studies revealed that while the base composition (percent of A, T, G, and C) varies greatly between distantly related organisms, in all organisms the percent of A always equals the percent of T, and the percent of G always equals the percent of C. Based on these discoveries and the structures of the four nucleotides, Watson and Crick performed careful molecular model building, proposing a **double helix**, with A always hydrogen-bonded to T and G always hydrogen-bonded to C at the axis of the double helix. The Watson and Crick model proved correct and paved the way for our modern understanding of how DNA functions as the genetic material. Today, our most accurate models for DNA structure come from high-resolution x-ray diffraction studies of crystals of DNA, made possible by the chemical synthesis of large amounts of short DNA molecules of uniform length and sequence that are amenable to crystallization (Figure 4-3a).

DNA consists of two associated polynucleotide strands that wind together to form a double helix. The two sugar-phosphate backbones are on the outside of the double helix, and the bases project into the interior. The adjoining bases in each strand stack on top of one another in parallel planes (Figure 4-3a). The orientation of the two strands is *antiparallel*; that is, their 5'→3' directions are opposite. The strands are held in precise register by formation of **base pairs** between the two strands: A is paired with T through two hydrogen bonds; G is paired with C through three hydrogen bonds (Figure 4-3b). This base-pair complementarity is a consequence of the size, shape, and chemical composition of the bases. The presence of thousands of such hydrogen bonds in a DNA molecule contributes greatly to the stability of the double helix. Hydrophobic and van der Waals interactions between the stacked adjacent base pairs further stabilize the double-helical structure.

In natural DNA, A always hydrogen bonds with T, and G with C, forming A·T and G·C base pairs as shown in Figure 4-3b. These associations, always between a larger purine and a smaller pyrimidine, are often called *Watson-Crick*

FIGURE 4-3 The DNA double helix. (a) Space-filling model of B DNA, the most common form of DNA in cells. The bases (light shades) project inward from the sugar-phosphate backbones (dark red and blue) of each strand, but their edges are accessible through major and minor grooves. Arrows indicate the 5'→3' direction of each strand. Hydrogen bonds between the bases are in the center of the structure. The major and minor grooves are lined by potential hydrogen bond donors and acceptors (highlighted in yellow). (b) Chemical structure of DNA double helix. This extended schematic shows the two sugar-phosphate backbones and hydrogen bonding between the Watson-Crick base pairs, A·T and G·C. [Part (a) adapted from R. Wing et al., 1980, *Nature* **287**:755. Part (b) adapted from R. E. Dickerson, 1983, *Sci. Am.* **249**:94.]

base pairs. Two polynucleotide strands, or regions thereof, in which all the nucleotides form such base pairs are said to be **complementary**. However, in theory and in synthetic DNAs, other base pairs can form. For example, guanine (a purine) could theoretically form hydrogen bonds with thymine (a pyrimidine), causing only a minor distortion in the helix. The space available in the helix also would allow pairing between the two pyrimidines cytosine and thymine. Although the nonstandard G·T and C·T base pairs are normally not found in DNA, G·U base pairs are quite common in double-helical regions that form within otherwise single-stranded RNA. Nonstandard base pairs do not occur naturally in duplex DNA because the DNA copying enzyme, which is described later in this chapter, does not permit them.

Most DNA in cells is a *right-handed* helix. The x-ray diffraction pattern of DNA indicates that the stacked bases are regularly spaced 0.34 nm apart along the helix axis. The helix makes a complete turn every 3.4 to 3.6 nm, depending on the sequence; thus there are about 10–10.5 base pairs per turn. This is referred to as the *B form* of DNA, the normal form present in most DNA stretches in cells. On the outside of B-form DNA, the spaces between the intertwined strands form two helical grooves of different widths described as the *major groove* and the *minor groove* (see Figure 4-3a). As a consequence, the atoms on the edges of each base within these grooves are accessible from outside the helix, forming two types of binding surfaces. DNA-binding proteins can “read” the sequence of bases in duplex DNA by contacting atoms in either the major or the minor grooves.

Under laboratory conditions in which most of the water is removed from DNA, the crystallographic structure of DNA changes to the *A form*, which is wider and shorter than B-form DNA, with a wider and deeper major groove and a more narrow and shallow minor groove (Figure 4-4). RNA-DNA and RNA-RNA helices exist in this form in cells and in vitro.

FIGURE 4-4 Comparison of A- and B-Form DNA. The sugar-phosphate backbones of the two strands, which are on the outside of both structures, are shown in red and blue; the bases (lighter shades) are oriented inward. (a) The B form of DNA has ≈10.5 base pairs per helical turn. Adjacent stacked base pairs are 0.34 nm apart. (b) The more compact A form of DNA has 11 base pairs per turn with a much deeper major groove and much more shallow minor groove than B form DNA.

Important modifications in the structure of standard B-form DNA come about as a result of protein binding to specific DNA sequences. Although the multitude of hydrogen and hydrophobic bonds between the bases provides stability to DNA, the double helix is flexible about its long axis. Unlike the α helix in proteins (see Figure 3-4), there are no hydrogen bonds parallel to the axis of the DNA helix. This property allows DNA to bend when complexed with a DNA-binding protein (Figure 4-5). Bending of DNA is critical to the dense packing of DNA in chromatin, the protein-DNA complex in which nuclear DNA occurs in eukaryotic cells (Chapter 6).

Why did DNA evolve to be the carrier of genetic information in cells as opposed to RNA? The hydrogen at the 2' position in the deoxyribose of DNA makes it a far more stable molecule than RNA, which instead has a hydroxyl group at the 2' position of ribose (see Figure 2-16). The 2'-hydroxyl groups in RNA participate in the slow, OH^- -catalyzed hydrolysis of phosphodiester bonds at neutral pH (Figure 4-6). The absence of 2'-hydroxyl groups in DNA prevents this process. Therefore, the presence of deoxyribose in DNA prevents this process. Therefore, the presence of deoxyribose in DNA makes it a more stable molecule—a characteristic that is critical to its function in the long-term storage of genetic information.

DNA Can Undergo Reversible Strand Separation

During replication and transcription of DNA, the strands of the double helix must separate to allow the internal edges of the bases to pair with the bases of the nucleotides being polymerized into new polynucleotide chains. In later sections,

FIGURE 4-5 Protein interaction can bend DNA. The conserved C-terminal domain of the TATA box-binding protein (TBP) binds to the minor groove of specific DNA sequences rich in A and T, untwisting and sharply bending the double helix. Transcription of most eukaryotic genes requires participation of TBP. [Adapted from D. B. Nikolov and S. K. Burley, 1997, *Proc. Nat'l Acad. Sci. USA* **94**:15.]

we describe the cellular mechanisms that separate and subsequently reassociate DNA strands during replication and transcription. Here we discuss fundamental factors that influence the separation and reassociation of DNA strands. These properties of DNA were elucidated by *in vitro* experiments.

FIGURE 4-6 Base-catalyzed hydrolysis of RNA. The 2'-hydroxyl group in RNA can act as a nucleophile, attacking the phosphodiester bond. The 2',3' cyclic monophosphate derivative is further hydrolyzed to a mixture of 2' and 3' monophosphates. This mechanism of

phosphodiester bond hydrolysis cannot occur in DNA, which lacks 2'-hydroxyl groups. [Adapted from Nelson et al., *Lehninger Principles of Biochemistry*, 4th ed., W. H. Freeman and Company.]

EXPERIMENTAL FIGURE 4-7 G·C content of DNA affects melting temperature. The temperature at which DNA denatures increases with the proportion of G·C pairs. (a) Melting of double-stranded DNA can be monitored by the absorption of ultraviolet light at 260 nm. As regions of double-stranded DNA unpair, the absorption of light by those regions increases almost twofold. The temperature at

which half the bases in a double-stranded DNA sample have denatured is denoted T_m (for “temperature of melting”). Light absorption by single-stranded DNA changes much less as the temperature is increased. (b) The T_m is a function of the G·C content of the DNA; the higher the G·C percentage, the greater the T_m .

The unwinding and separation of DNA strands, referred to as **denaturation**, or “melting,” can be induced experimentally by increasing the temperature of a solution of DNA. As the thermal energy increases, the resulting increase in molecular motion eventually breaks the hydrogen bonds and other forces that stabilize the double helix; the strands then separate, driven apart by the electrostatic repulsion of the negatively charged deoxyribose-phosphate backbone of each strand. Near the denaturation temperature, a small increase in temperature causes a rapid, nearly simultaneous loss of the multiple weak interactions holding the strands together along the entire length of the DNA molecules. Because the stacked base pairs in duplex DNA absorb less ultraviolet (UV) light than the unstacked bases in single-stranded DNA, this leads to an abrupt increase in the absorption of UV light, a phenomenon known as *hyperchromicity* (Figure 4-7a).

The *melting temperature* (T_m) at which DNA strands will separate depends on several factors. Molecules that contain a greater proportion of G·C pairs require higher temperatures to denature because the three hydrogen bonds in G·C pairs make these base pairs more stable than A·T pairs, which have only two hydrogen bonds. Indeed, the percentage of G·C base pairs in a DNA sample can be estimated from its T_m (Figure 4-7b). The ion concentration also influences the T_m because the negatively charged phosphate groups in the two strands are shielded by positively charged ions. When the ion concentration is low, this shielding is decreased, thus increasing the repulsive forces between the strands and reducing the T_m . Agents that destabilize hydrogen bonds, such as formamide or urea, also lower the T_m . Finally, extremes of pH denature DNA at low temperature. At low (acid) pH, the bases become protonated and thus positively charged, repelling each other. At high (alkaline) pH, the bases lose protons and become negatively charged,

again repelling each other because of the similar charge. In cells, pH and temperature are, for the most part, maintained. These features of DNA separation are most useful for manipulating DNA in a laboratory setting.

The single-stranded DNA molecules that result from denaturation form random coils without an organized structure. Lowering the temperature, increasing the ion concentration, or neutralizing the pH causes the two complementary strands to reassociate into a perfect double helix. The extent of such *renaturation* is dependent on time, the DNA concentration, and the ionic concentration. Two DNA strands that are not related in sequence will remain as random coils and will not renature; most importantly, they will not inhibit complementary DNA partner strands from finding each other and renaturing. Denaturation and renaturation of DNA are the basis of nucleic acid **hybridization**, a powerful technique used to study the relatedness of two DNA samples and to detect and isolate specific DNA molecules in a mixture containing numerous different DNA sequences (see Figure 5-16).

Torsional Stress in DNA Is Relieved by Enzymes

Many bacterial genomic DNAs and many viral DNAs are circular molecules. Circular DNA molecules also occur in mitochondria, which are present in almost all eukaryotic cells, and in chloroplasts, which are present in plants and some unicellular eukaryotes.

Each of the two strands in a circular DNA molecule forms a closed structure without free ends. Localized unwinding of a circular DNA molecule, which occurs during DNA replication, induces torsional stress into the remaining portion of the molecule because the ends of the strands are not free to rotate. As a result, the DNA molecule twists back

EXPERIMENTAL FIGURE 4-8

Topoisomerase I relieves torsional stress on DNA. (a) Electron micrograph of SV40 viral DNA. When the circular DNA of the SV40 virus is isolated and separated from its associated protein, the DNA duplex is underwound and assumes the supercoiled configuration. (b) If a supercoiled DNA is nicked (i.e., one strand cleaved), the strands can rewind, leading to loss of a supercoil. Topoisomerase I catalyzes this reaction and also reseals the broken ends. All the supercoils in isolated SV40 DNA can be removed by the sequential action of this enzyme, producing the relaxed-circle conformation. For clarity, the shapes of the molecules at the bottom have been simplified.

on itself, like a twisted rubber band, forming *supercoils* (Figure 4-8a). In other words, when part of the DNA helix is underwound, left-handed supercoils are introduced into the circular DNA molecule, as in Figure 4-8a. Bacterial and eukaryotic cells, however, contain *topoisomerase I*, which can relieve any torsional stress that develops in cellular DNA molecules during replication or other processes. This enzyme binds to DNA at random sites and breaks a phosphodiester bond in one strand. Such a one-strand break in DNA is called a *nick*. The broken end then winds around the uncut strand, leading to loss of supercoils (Figure 4-8b). Finally, the same enzyme joins (ligates) the two ends of the broken strand. Another type of enzyme, *topoisomerase II*, makes breaks in both strands of a double-stranded DNA and then religates them. As a result, topoisomerase II can both relieve torsional stress and link together two circular DNA molecules as in the links of a chain.

Although eukaryotic nuclear DNA is linear, long loops of DNA are fixed in place within chromosomes (Chapter 6). Thus torsional stress and the consequent formation of supercoils also could occur during replication of nuclear DNA. As in bacterial cells, abundant topoisomerase I in eukaryotic nuclei relieves any torsional stress in nuclear DNA that would develop in the absence of this enzyme.

Different Types of RNA Exhibit Various Conformations Related to Their Functions

The primary structure of RNA is generally similar to that of DNA with two exceptions: the sugar component of RNA, ribose, has a hydroxyl group at the 2' position (see Figure 2-16b), and thymine in DNA is replaced by uracil in RNA.

The presence of thymine rather than uracil in DNA is important to the long-term stability of DNA because of its function in DNA repair (see Section 4.7). As noted earlier, the hydroxyl group on the 2' C of ribose makes RNA more chemically labile than DNA. As a result of this lability, RNA is cleaved into mononucleotides by alkaline solution (see Figure 4-6), whereas DNA is not. The 2'-C hydroxyl of RNA also provides a chemically reactive group that takes part in RNA-mediated catalysis. Like DNA, RNA is a long polynucleotide that can be double-stranded or single-stranded, linear or circular. It can also participate in a hybrid helix composed of one RNA strand and one DNA strand. As discussed above, RNA-RNA and RNA-DNA double helices have a compact conformation like the A form of DNA (see Figure 4-4b).

Unlike DNA, which exists primarily as a very long double helix, most cellular RNAs are single-stranded and exhibit a variety of conformations (Figure 4-9). Differences in the sizes and conformations of the various types of RNA permit them to carry out specific functions in a cell. The simplest secondary structures in single-stranded RNAs are formed by pairing of complementary bases. "Hairpins" are formed by pairing of bases within ≈ 5 –10 nucleotides of each other, and "stem-loops" by pairing of bases that are separated by >10 to several hundred nucleotides. These simple folds can cooperate to form more complicated tertiary structures, one of which is termed a "pseudoknot."

As discussed in detail later, tRNA molecules adopt a well-defined three-dimensional architecture in solution that is crucial in protein synthesis. Larger rRNA molecules also have locally well-defined three-dimensional structures, with more flexible linkers in between. Secondary and tertiary structures

(a) Secondary structure

The diagram illustrates two types of secondary structure elements in a polynucleotide chain. On the left, a 'Hairpin' structure is shown as a red line that folds back on itself, forming a double-stranded stem (indicated by blue lines) and a single-stranded loop. On the right, a 'Stem-loop' structure is shown as a red line that forms a large loop with a double-stranded stem (indicated by blue lines) at its base. The labels 'Hairpin' and 'Stem-loop' are placed below their respective structures. The text 'Double-helical stem region' is placed to the right of the stem in the stem-loop structure.

[illegible]

also have been recognized in mRNA, particularly near the ends of molecules. Clearly, then, RNA molecules are like proteins in that they have structured domains connected by less structured, flexible stretches.

during formation of the majority of functional mRNA molecules in multicellular eukaryotes, and also occurs in single-celled eukaryotes such as yeast, bacteria, and archaea. Remarkably, some RNAs carry out *self-splicing*, with the catalytic activity residing in the sequence that is removed. The mechanisms of splicing and self-splicing are discussed in detail in Chapter 8. As noted later in this chapter, rRNA plays a catalytic role in the formation of peptide bonds during protein synthesis.

In this chapter, we focus on the functions of mRNA, tRNA, and rRNA in gene expression. In later chapters we will encounter other RNAs, often associated with proteins, that participate in other cell functions.

Structure of Nucleic Acids

- 4.1 Structure of Nucleic Acids 123

- Circular DNA molecules can be twisted on themselves, forming supercoils (see Figure 4-8). Enzymes called topoisomerases can relieve torsional stress and remove supercoils from circular DNA molecules. Long linear DNA can also experience torsional stress because long loops are fixed in place within chromosomes.
- Cellular RNAs are single-stranded polynucleotides, some of which form well-defined secondary and tertiary structures (see Figure 4-9). Some RNAs, called ribozymes, have catalytic activity.

4.2 Transcription of Protein-Coding Genes and Formation of Functional mRNA

The simplest definition of a gene is a “unit of DNA that contains the information to specify synthesis of a single polypeptide chain or functional RNA (such as a tRNA).” The DNA molecules of small viruses contain only a few genes, whereas the single DNA molecule in each of the chromosomes of higher animals and plants may contain several thousand genes. The vast majority of genes carry information to build protein molecules, and it is the RNA copies of such *protein-coding genes* that constitute the mRNA molecules of cells.

During synthesis of RNA, the four-base language of DNA containing A, G, C, and T is simply copied, or *transcribed*, into the four-base language of RNA, which is identical except that U replaces T. In contrast, during protein synthesis, the four-base language of DNA and RNA is *translated* into the 20-amino acid language of proteins. In this section, we focus on formation of functional mRNAs from protein-coding genes (see Figure 4-1, step 1). A similar process yields the precursors of rRNAs and tRNAs encoded by rRNA and tRNA genes; these precursors are then further modified to yield functional rRNAs and tRNAs (Chapter 8). Similarly, thousands of *micro RNAs* (miRNAs) that regulate translation of specific target mRNAs are transcribed into precursors by RNA polymerases and processed into functional miRNAs (Chapter 8). Other non-protein-coding (or simply “noncoding”) RNAs help to regulate transcription of specific protein-coding genes. Regulation of transcription allows distinct sets of genes to be expressed in the multiple different types of cells that make up a multicellular organism. It also allows different amounts of mRNA to be transcribed from different genes, resulting in differences in the amounts of the encoded proteins in a cell. Regulation of transcription is addressed in Chapter 7.

A Template DNA Strand Is Transcribed into a Complementary RNA Chain by RNA Polymerase

During transcription of DNA, one DNA strand acts as a *template*, determining the order in which ribonucleoside triphosphate (rNTP) monomers are polymerized to form a

complementary RNA chain. Bases in the template DNA strand base-pair with complementary incoming rNTPs, which then are joined in a polymerization reaction catalyzed by **RNA polymerase**. Polymerization involves a nucleophilic attack by the 3' oxygen in the growing RNA chain on the α phosphate of the next nucleotide precursor to be added, resulting in formation of a phosphodiester bond and release of pyrophosphate (PP_i). As a consequence of this mechanism, RNA molecules are always synthesized in the 5'→3' direction (Figure 4-10a).

The energetics of the polymerization reaction strongly favors addition of ribonucleotides to the growing RNA chain because the high-energy bond between the α and β phosphates of rNTP monomers is replaced by the lower-energy phosphodiester bond between nucleotides. The equilibrium for the reaction is driven further toward chain elongation by pyrophosphatase, an enzyme that catalyzes cleavage of the released PP_i into two molecules of inorganic phosphate. Like the two strands in DNA, the template DNA strand and the growing RNA strand that is base-paired to it have opposite 5'→3' directionality.

By convention, the site on the DNA at which RNA polymerase begins transcription is numbered +1 (Figure 4-10b). *Downstream* denotes the direction in which a template DNA strand is transcribed; *upstream* denotes the opposite direction. Nucleotide positions in the DNA sequence downstream from a start site are indicated by a positive (+) sign; those upstream, by a negative (−) sign. Because RNA is synthesized 5'→3', RNA polymerase moves down the template DNA strand in a 3'→5' direction. The newly synthesized RNA is complementary to the template DNA strand; therefore it is identical to the nontemplate DNA strand, with uracil in place of thymine.

Stages in Transcription To carry out transcription, RNA polymerase performs several distinct functions, as depicted in Figure 4-11. During transcription *initiation*, RNA polymerase, with the help of initiation factors discussed later, recognizes and binds to a specific site, called a **promoter**, in double-stranded DNA (step 1). After binding, RNA polymerase and the initiation factors separate the DNA strands to make the bases in the template strand available for base pairing with the bases of the ribonucleoside triphosphates that it will polymerize. RNA polymerases and initiation factors then melt 12–14 base pairs of DNA around the transcription start site, which is located on the template strand within the promoter region (step 2). This allows the template strand to enter the active site of the enzyme that catalyzes phosphodiester bond formation between ribonucleotide triphosphates that are complementary to the promoter template strand at the start site of transcription. The 12- to 14-base-pair region of melted DNA in the polymerase is known as the *transcription bubble*. Transcription initiation is considered complete when the first two ribonucleotides of an RNA chain are linked by a phosphodiester bond (step 3).

After several ribonucleotides have been polymerized, RNA polymerase dissociates from the promoter DNA and

general transcription factors. During the stage of *strand elongation*, RNA polymerase moves along the template DNA one base at a time, opening the double-stranded DNA in front of its direction of movement and guiding the strands together so that they hybridize at the upstream end of the transcription bubble (Figure 4-11, step 4). One ribonucleotide at a time is added to the 3' end of the growing (*nascent*) RNA chain during strand elongation by the polymerase. The enzyme maintains a melted region of approximately 14 base pairs in the transcription bubble. Approximately eight nucleotides at the 3' end of the growing RNA strand remain base-paired to the template DNA strand in the transcription bubble. The elongation complex, comprising RNA polymerase, template DNA, and the growing (*nascent*) RNA strand, is extraordinarily stable. For example, RNA polymerase transcribes the longest known mammalian gene, containing about 2 million base pairs, without dissociating from

FIGURE 4-10 RNA is synthesized 5'→3'. (a) Polymerization of ribonucleotides by RNA polymerase during transcription. The ribonucleotide to be added at the 3' end of a growing RNA strand is specified by base pairing between the next base in the template DNA strand and the complementary incoming ribonucleoside triphosphate (rNTP). A phosphodiester bond is formed when RNA polymerase catalyzes a reaction between the 3' O of the growing strand and the α phosphate of a correctly base-paired rNTP. RNA strands always are synthesized in the 5'→3' direction and are opposite in polarity to their template DNA strands. (b) Conventions for describing RNA transcription. *Top:* The DNA nucleotide where RNA polymerase begins transcription is designated +1. The direction the polymerase travels on the DNA is "downstream," and bases are marked with positive numbers. The opposite direction is "upstream," and bases are noted with negative numbers. Some important gene features lie upstream of the transcription start site, including the promoter sequence that localizes RNA polymerase to the gene. (*Bottom:*) The DNA strand that is being transcribed is the template strand; its complement, the nontemplate strand. The RNA being synthesized is complementary to the template strand, and therefore identical with the nontemplate strand sequence, except with uracil in place of thymine. [Part (b) adapted from Griffiths et al., *Modern Genetic Analysis*, 2d ed., W. H. Freeman and Company.]

FIGURE 4-11 Three stages in transcription. During initiation of transcription, RNA polymerase forms a transcription bubble and begins polymerization of ribonucleotides (rNTPs) at the start site, which is located within the promoter region. Once a DNA region has been transcribed, the separated strands reassociate into a double helix. The nascent RNA is displaced from its template strand except at its 3' end. The 5' end of the RNA strand exits the RNA polymerase through a channel in the enzyme. Termination occurs when the polymerase encounters a specific termination sequence (stop site). See the text for details. For simplicity, the diagram depicts transcription of four turns of the DNA helix encoding ≈ 40 nucleotides of RNA. Most RNAs are considerably longer, requiring transcription of a longer region of DNA.

the DNA template or releasing the nascent RNA. RNA synthesis occurs at a rate of about 1000 nucleotides per minute at 37 °C, so the elongation complex must remain intact for more than 24 hours to assure continuous RNA synthesis of the pre-mRNA from this very long gene.

During transcription *termination*, the final stage in RNA synthesis, the completed RNA molecule is released from the RNA polymerase and the polymerase dissociates from the template DNA (Figure 4-11, step **5**). Once it is released, an RNA polymerase is free to transcribe the same gene again or another gene.

Structure of RNA Polymerases The RNA polymerases of bacteria, archaea, and eukaryotic cells are fundamentally similar in structure and function. Bacterial RNA polymerases are composed of two related large subunits (β' and β), two copies of a smaller subunit (α), and one copy of a fifth

subunit (ω) that is not essential for transcription or cell viability but that stabilizes the enzyme and assists in the assembly of its subunits. Archaeal and eukaryotic RNA polymerases have several additional small subunits associated with this core complex, which we describe in Chapter 7. Schematic diagrams of the transcription process generally show RNA polymerase bound to an unbent DNA molecule, as in Figure 4-11. However, x-ray crystallography and other studies of an elongating bacterial RNA polymerase indicate that the DNA bends at the transcription bubble (Figure 4-12).

Organization of Genes Differs in Prokaryotic and Eukaryotic DNA

Having outlined the process of transcription, we now briefly consider the large-scale arrangement of information in DNA and how this arrangement dictates the requirements for

FIGURE 4-12 Bacterial RNA polymerase. This structure corresponds to the polymerase molecule in the elongation phase (step 4) of Figure 4-11. In these diagrams, transcription is proceeding in the leftward direction. Arrows indicate where downstream DNA enters the polymerase and upstream DNA exits at an angle from the downstream DNA; the coding strand is red, the noncoding strand blue; nascent RNA green. The RNA polymerase β' subunit is gold, β is light gray, and the α subunit visible from this angle brown. The upper diagram is a space-filling model of the elongation complex viewed from an angle that emphasizes the bend in the DNA as it passes through the polymerase. The elongation complex is rotated in the bottom diagram as shown, and proteins are made largely transparent to reveal the structure of the transcription bubble inside the polymerase that is not visible in the space-filling model. Nucleotides complementary to the template DNA are added to the 3' end of the nascent RNA strand (at the left). The newly synthesized nascent RNA exits the polymerase at the bottom through a channel formed between the β and β' subunits. The ω subunit and the other α subunit are visible from this angle. [Courtesy of Seth Darst; see N. Korzheva et al., 2000, *Science* **289**:619–625, and N. Opalka et al., 2003, *Cell* **114**:335–345.]

RNA synthesis so that information transfer goes smoothly. In recent years, sequencing of the entire **genomes** from multiple organisms has revealed not only large variations in the number of protein-coding genes but also differences in their organization in bacteria and eukaryotes.

The most common arrangement of protein-coding genes in all bacteria has a powerful and appealing logic: genes encoding proteins that function together, for example, the enzymes required to synthesize the amino acid tryptophan, are most often found in a contiguous array in the DNA. Such an arrangement of genes in a functional group is called an **operon**, because it operates as a unit from a single promoter. Transcription of an operon produces a continuous strand of mRNA that carries the message for a related series of proteins (Figure 4-13a). Each section of the mRNA represents the unit (or gene) that encodes one of the proteins in the series. This arrangement results in the *coordinate expression* of all the genes in the operon. Every time an RNA polymerase molecule initiates transcription at the promoter of the operon, all the genes of the operon are transcribed and translated. In prokaryotic DNA the genes are closely packed with very few noncoding gaps, and the DNA is transcribed directly into mRNA. Because DNA is not sequestered in a nucleus in prokaryotes, ribosomes have immediate access to the translation start sites in the mRNA as they emerge from the surface of the RNA polymerase. Consequently, translation of the mRNA begins even while the 3' end of the mRNA is still being synthesized at the active site of the RNA polymerase.

This economic clustering of genes devoted to a single metabolic function does not occur in eukaryotes, even simple ones such as yeasts, which can be metabolically similar to bacteria. Rather, eukaryotic genes encoding proteins that function together are most often physically separated in the DNA; indeed, such genes usually are located on different chromosomes. Each gene is transcribed from its own promoter, producing one mRNA, which generally is translated to yield a single polypeptide (Figure 4-13b).

When researchers first compared the nucleotide sequences of eukaryotic mRNAs from multicellular organisms with the DNA sequences encoding them, they were surprised to find that the uninterrupted protein-coding sequence of a given mRNA was discontinuous in its corresponding section of DNA. They concluded that the eukaryotic gene existed in pieces of coding sequence, the **exons**, separated by non-protein-coding segments, the **introns**. This astonishing finding implied that introns are removed from the long initial **primary transcript**—the RNA copy of the entire transcribed DNA sequence—and the remaining exons are spliced together to produce eukaryotic mRNAs.

Although introns are common in multicellular eukaryotes, they are extremely rare in bacteria and archaea and uncommon in many unicellular eukaryotes such as baker's yeast. However, introns are present in the DNA of viruses that infect eukaryotic cells. Indeed, the presence of introns was first discovered in such viruses, whose DNA is transcribed by host-cell enzymes.

(a) Prokaryotes

FIGURE 4-13 Gene organization in prokaryotes and eukaryotes.

(a) The tryptophan (*trp*) operon is a continuous segment of the *E. coli* chromosome, containing five genes (blue) that encode the enzymes necessary for the stepwise synthesis of tryptophan. The entire operon is transcribed from one promoter into one long continuous *trp* mRNA (red). Translation of this mRNA begins at five different start sites, yielding five proteins (green). The order of the genes in the bacterial

(b) Eukaryotes

genome parallels the sequential function of the encoded proteins in the tryptophan pathway. (b) The five genes encoding the enzymes required for tryptophan synthesis in yeast (*Saccharomyces cerevisiae*) are carried on four different chromosomes. Each gene is transcribed from its own promoter to yield a primary transcript that is processed into a functional mRNA encoding a single protein. The lengths of the various chromosomes are given in kilobases (10^3 bases).

Eukaryotic Precursor mRNAs Are Processed to Form Functional mRNAs

In bacterial cells, which have no nuclei, translation of an mRNA into protein can begin from the 5' end of the mRNA even while the 3' end is still being synthesized by RNA polymerase. In other words, transcription and translation occur concurrently in bacteria. In eukaryotic cells, however, not only is the site of RNA synthesis—the nucleus—separated from the site of translation—the cytoplasm—but also the primary transcripts of protein-coding genes are precursor mRNAs (pre-mRNAs) that must undergo several modifications, collectively termed *RNA processing*, to yield a functional mRNA (see Figure 4-1, step 2). This mRNA then must be exported to the cytoplasm before it can be translated into protein. Thus transcription and translation cannot occur concurrently in eukaryotic cells.

All eukaryotic pre-mRNAs initially are modified at the two ends, and these modifications are retained in mRNAs. As the 5' end of a nascent RNA chain emerges from the surface of RNA polymerase, it is immediately acted on by several enzymes that together synthesize the 5' cap, a 7-methylguanylate

that is connected to the terminal nucleotide of the RNA by an unusual 5',5' triphosphate linkage (Figure 4-14). The cap protects an mRNA from enzymatic degradation and assists in its export to the cytoplasm. The cap also is bound by a protein factor required to begin translation in the cytoplasm.

Processing at the 3' end of a pre-mRNA involves cleavage by an endonuclease to yield a free 3'-hydroxyl group to which a string of adenylic acid residues is added one at a time by an enzyme called *poly(A) polymerase*. The resulting *poly(A) tail* contains 100–250 bases, being shorter in yeasts and invertebrates than in vertebrates. Poly(A) polymerase is part of a complex of proteins that can locate and cleave a transcript at a specific site and then add the correct number of A residues, in a process that does not require a template.

Another step in the processing of many different eukaryotic mRNA molecules is *RNA splicing*: the internal cleavage of a transcript to excise the introns and stitch together the coding exons. Figure 4-15 summarizes the basic steps in eukaryotic mRNA processing, using the β -globin gene as an example. We examine the cellular machinery for carrying out processing of mRNA, as well as tRNA and rRNA, in Chapter 8.

FIGURE 4-14 Structure of the 5' methylated cap. The distinguishing chemical features of the 5' methylated cap on eukaryotic mRNA are (1) the 5'→5' linkage of 7-methylguanylate to the initial nucleotide of the mRNA molecule and (2) the methyl group on the 2' hydroxyl of the ribose of the first nucleotide (base 1). Both these features occur in all animal cells and in cells of higher plants; yeasts lack the methyl group on nucleotide 1. The ribose of the second nucleotide (base 2) also is methylated in vertebrates. [See A. J. Shatkin, 1976, *Cell* 9:645.]

The functional eukaryotic mRNAs produced by RNA processing retain noncoding regions, referred to as 5' and 3' *untranslated regions (UTRs)*, at each end. In mammalian mRNAs, the 5' UTR may be a hundred or more nucleotides long, and the 3' UTR may be several kilobases in length. Bacterial mRNAs also usually have 5' and 3' UTRs, but these are much shorter than those in eukaryotic mRNAs, generally containing fewer than 10 nucleotides.

Alternative RNA Splicing Increases the Number of Proteins Expressed from a Single Eukaryotic Gene

In contrast to bacterial and archaeal genes, the vast majority of genes in higher, multicellular eukaryotes contain multiple introns. As noted in Chapter 3, many proteins from higher eukaryotes have a multidomain tertiary structure (see Figure 3-11). Individual repeated protein domains often are

OVERVIEW ANIMATION: Life Cycle of an mRNA

FIGURE 4-15 Overview of RNA processing. RNA processing produces functional mRNA in eukaryotes. The β -globin gene contains three protein-coding exons (constituting the coding region, red) and two intervening noncoding introns (blue). The introns interrupt the protein-coding sequence between the codons for amino acids 31 and 32 and 105 and 106. Transcription of eukaryotic protein-coding genes starts before the sequence that encodes the first amino acid and extends beyond the sequence encoding the last amino acid, resulting in noncoding regions (gray) at the ends of the primary transcript. These untranslated regions (UTRs) are retained during processing. The 5' cap (m^7Gppp) is added during formation of the primary RNA transcript, which extends beyond the poly(A) site. After cleavage at the poly(A) site and addition of multiple A residues to the 3' end, splicing removes the introns and joins the exons. The small numbers refer to positions in the 147-amino acid sequence of β -globin.

FIGURE 4-16 Alternative splicing. The ≈ 75 -kb fibronectin gene (top) contains multiple exons; splicing of fibronectin varies by cell type. The EIIIB and EIIB exons (green) encode binding domains for specific proteins on the surface of fibroblasts. The fibronectin mRNA produced

in fibroblasts includes the EIIIB and EIIB exons, whereas these exons are spliced out of fibronectin mRNA in hepatocytes. In this diagram, introns (black lines) are not drawn to scale; most of them are much longer than any of the exons.

encoded by one exon or a small number of exons that code for identical or nearly identical amino acid sequences. Such repeated exons are thought to have evolved by the accidental multiple duplication of a length of DNA lying between two sites in adjacent introns, resulting in insertion of a string of repeated exons, separated by introns, between the original two introns. The presence of multiple introns in many eukaryotic genes permits expression of multiple, related proteins from a single gene by means of **alternative splicing**. In higher eukaryotes, alternative splicing is an important mechanism for production of different forms of a protein, called **isoforms**, by different types of cells.

Fibronectin, a multidomain protein found in mammals, provides a good example of alternative splicing (Figure 4-16). Fibronectin is a long, adhesive protein secreted into the extracellular space that can bind other proteins together. What and where it binds depends on which domains are spliced together. The fibronectin gene contains numerous exons, grouped into several regions corresponding to specific domains of the protein. Fibroblasts produce fibronectin mRNAs that contain exons EIIIB and EIIB; these exons encode amino acid sequences that bind tightly to proteins in the fibroblast plasma membrane. Consequently, this fibronectin isoform adheres fibroblasts to the extracellular matrix. Alternative splicing of the fibronectin primary transcript in hepatocytes, the major type of cell in the liver, yields mRNAs that lack the EIIIB and EIIB exons. As a result, the fibronectin secreted by hepatocytes into the blood does not adhere tightly to fibroblasts or most other cell types, allowing it to circulate. During formation of blood clots, however, the fibrin-binding domains of hepatocyte fibronectin binds to fibrin, one of the principal constituents of clots. The bound fibronectin then interacts with integrins on the membranes of passing platelets, thereby expanding the clot by addition of platelets.

More than 20 different isoforms of fibronectin have been identified, each encoded by a different, alternatively spliced mRNA composed of a unique combination of fibronectin gene exons. Sequencing of large numbers of mRNAs isolated from various tissues and comparison of their sequences with genomic DNA has revealed that nearly 90 percent of all human genes are expressed as alternatively spliced mRNAs.

Clearly, alternative RNA splicing greatly expands the number of proteins encoded by the genomes of higher, multicellular organisms.

KEY CONCEPTS of Section 4.2

Transcription of Protein-Coding Genes and Formation of Functional mRNA

- Transcription of DNA is carried out by RNA polymerase, which adds one ribonucleotide at a time to the 3' end of a growing RNA chain (see Figure 4-11). The sequence of the template DNA strand determines the order in which ribonucleotides are polymerized to form an RNA chain.
- During transcription initiation, RNA polymerase binds to a specific site in DNA (the promoter), locally melts the double-stranded DNA to reveal the unpaired template strand, and polymerizes the first two nucleotides complementary to the template strand. The melted region of 12–14 base pairs is known as the transcription bubble.
- During strand elongation, RNA polymerase moves down the DNA, melting the DNA ahead of the polymerase so that the template strand can enter the active site of the enzyme and allowing the complementary strands of the region just transcribed to reanneal behind it. The transcription bubble moves with the polymerase as the enzyme adds ribonucleotides complementary to the template strand to the 3' end of the growing RNA chain.
- When RNA polymerase reaches a termination sequence in the DNA, the enzyme stops transcription, leading to release of the completed RNA and dissociation of the enzyme from the template DNA.
- In prokaryotic DNA, several protein-coding genes commonly are clustered into a functional region, an operon, which is transcribed from a single promoter into one mRNA encoding multiple proteins with related functions (see Figure 4-13a). Translation of a bacterial mRNA can begin before synthesis of the mRNA is complete.

- In eukaryotic DNA, each protein-coding gene is transcribed from its own promoter. The initial primary transcript very often contains noncoding regions (introns) interspersed among coding regions (exons).
- Eukaryotic primary transcripts must undergo RNA processing to yield functional RNAs. During processing, the ends of nearly all primary transcripts from protein-coding genes are modified by addition of a 5' cap and 3' poly(A) tail. Transcripts from genes containing introns undergo splicing, the removal of the introns and joining of the exons (see Figure 4-15).
- The individual domains of multidomain proteins found in higher eukaryotes are often encoded by individual exons or a small number of exons. Distinct isoforms of such proteins often are expressed in specific cell types as the result of alternative splicing of exons.

4.3 The Decoding of mRNA by tRNAs

Although DNA stores the information for protein synthesis and mRNA conveys the instructions encoded in DNA, most biological activities are carried out by proteins. As we saw in Chapter 3, the linear order of amino acids in each protein determines its three-dimensional structure and activity. For this reason, assembly of amino acids in their correct order, as encoded in DNA, is critical to production of functional proteins and hence the proper functioning of cells and organisms.

Translation is the whole process by which the nucleotide sequence of an mRNA is used as a template to join the amino acids in a polypeptide chain in the correct order (see Figure 4-1, step 3). In eukaryotic cells, protein synthesis occurs in the cytoplasm, where three types of RNA molecules come together to perform different but cooperative functions (Figure 4-17):

1. **Messenger RNA (mRNA)** carries the genetic information transcribed from DNA in a linear form. The mRNA is read in sets of three-nucleotide sequences, called **codons**, each of which specifies a particular amino acid.
2. **Transfer RNA (tRNA)** is the key to deciphering the codons in mRNA. Each type of amino acid has its own subset of tRNAs, which bind the amino acid and carry it to the growing end of a polypeptide chain when the next codon in the mRNA calls for it. The correct tRNA with its attached amino acid is selected at each step because each specific tRNA molecule contains a three-nucleotide sequence, an **anticodon**, that can base-pair with its complementary codon in the mRNA.
3. **Ribosomal RNA (rRNA)** associates with a set of proteins to form **ribosomes**. These complex structures, which physically move along an mRNA molecule, catalyze the assembly of amino acids into polypeptide chains. They also bind

FIGURE 4-17 The three roles of RNA in protein synthesis.

Messenger RNA (mRNA) is translated into protein by the joint action of transfer RNA (tRNA) and the ribosome, which is composed of numerous proteins and three (bacterial) or four (eukaryotic) ribosomal RNA (rRNA) molecules (not shown). Note the base pairing between tRNA anticodons and complementary codons in the mRNA. Formation of a peptide bond between the amino-group N on the incoming aa-tRNA and the carboxy-terminal C on the growing protein chain (green) is catalyzed by one of the rRNAs. aa = amino acid; R = side group. [Adapted from A. J. F. Griffiths et al., 1999, *Modern Genetic Analysis*, W. H. Freeman and Company.]

tRNAs and various accessory proteins necessary for protein synthesis. Ribosomes are composed of a large and a small subunit, each of which contains its own rRNA molecule or molecules.

These three types of RNA participate in the synthesis of proteins in all organisms. In this section, we focus on the decoding of mRNA by tRNA adaptors, and how the structure of each of these RNAs relates to its specific task. How they work together with rRNA, ribosomes, and other protein factors to synthesize proteins is detailed in the following section. Because translation is essential for protein synthesis, the two processes commonly are referred to interchangeably. However, the polypeptide chains resulting from translation undergo post-translational folding and often other changes (e.g., chemical modifications, association with other chains) that are required for production of mature, functional proteins (Chapter 3).

Messenger RNA Carries Information from DNA in a Three-Letter Genetic Code

As noted above, the genetic code used by cells is a *triplet* code, with every three-nucleotide sequence, or codon, being “read” from a specified starting point in the mRNA. Of the 64 possible codons in the genetic code, 61 specify individual amino acids and three are stop codons. Table 4-1 shows that most amino acids are encoded by more than one codon.

TABLE 4-1 The Genetic Code (Codons to Amino Acids)*

		Second Position				
		U	C	A	G	
First Position (5' End)	U	Phe	Ser	Tyr	Cys	U
		Phe	Ser	Tyr	Cys	C
		Leu	Ser	Stop	Stop	A
		Leu	Ser	Stop	Trp	G
	C	Leu	Pro	His	Arg	U
		Leu	Pro	His	Arg	C
		Leu	Pro	Gln	Arg	A
		Leu (Met)*	Pro	Gln	Arg	G
	A	Ile	Thr	Asn	Ser	U
		Ile	Thr	Asn	Ser	C
		Ile	Thr	Lys	Arg	A
		Met (Start)	Thr	Lys	Arg	G
	G	Val	Ala	Asp	Gly	U
		Val	Ala	Asp	Gly	C
		Val	Ala	Glu	Gly	A
		Val (Met)*	Ala	Glu	Gly	G

*AUG is the most common initiator codon; GUG usually codes for valine and CUG for leucine, but, rarely, these codons can also code for methionine to initiate a protein chain.

Only two—methionine and tryptophan—have a single codon; at the other extreme, leucine, serine, and arginine are each specified by six different codons. The different codons for a given amino acid are said to be synonymous. The code itself is termed *degenerate*, meaning that a particular amino acid can be specified by multiple codons.

Synthesis of all polypeptide chains in prokaryotic and eukaryotic cells begins with the amino acid methionine. In bacteria, a specialized form of methionine is used with a formyl group linked to its amino group. In most mRNAs, the *start (initiator) codon* specifying this amino-terminal methionine is AUG. In a few bacterial mRNAs, GUG is used as the initiator codon, and CUG occasionally is used as an initiator codon for methionine in eukaryotes. The three codons UAA, UGA, and UAG do not specify amino acids but constitute *stop (termination) codons* that mark the carboxyl terminus of polypeptide chains in almost all cells. The sequence of codons that runs from a specific start codon to a stop codon is called a **reading frame**. This precise linear array of ribonucleotides in groups of three in mRNA specifies the precise

linear sequence of amino acids in a polypeptide chain and also signals where synthesis of the chain starts and stops.

Because the genetic code is a non-overlapping triplet code without divisions between codons, a particular mRNA theoretically could be translated in three different reading frames. Indeed, some mRNAs have been shown to contain overlapping information that can be translated in different reading frames, yielding different polypeptides (Figure 4-18). The vast majority of mRNAs, however, can be read in only one frame because stop codons encountered in the other two possible reading frames terminate translation before a functional protein is produced. Very rarely, another unusual coding arrangement occurs because of *frame-shifting*. In this case the protein-synthesizing machinery may read four nucleotides as one amino acid and then continue reading triplets, or it may back up one base and read all succeeding triplets in the new frame until termination of the chain occurs. Only a few dozen such instances are known.

The meaning of each codon is the same in most known organisms—a strong argument that life on earth evolved

FIGURE 4-18 Multiple reading frames in an mRNA sequence. If translation of the mRNA sequence shown begins at three different upstream start sites (not shown), then three overlapping reading frames are possible. In this example, the codons are shifted one base to the right in the middle frame and two bases to the right in the third frame, which ends in a stop codon. As a result, the same nucleotide sequence specifies different amino acids during translation. Although regions of sequence that are translated in two of the three possible reading frames are rare, there are examples in both prokaryotes and eukaryotes, and especially in their viruses, where the same sequence is used in two alternative mRNAs expressed from the same region of DNA, and the sequence is read in one reading frame in one mRNA and in an alternative reading frame in the other mRNA. There are even a few instances where the same short sequence is read in all three possible reading frames.

only once. In fact, the genetic code shown in Table 4-1 is known as the *universal code*. However, the genetic code has been found to differ for a few codons in many mitochondria, in ciliated protozoans, and in *Acetabularia*, a single-celled plant. As shown in Table 4-2, most of these changes involve reading of normal stop codons as amino acids, not an exchange of one amino acid for another. These exceptions to the universal code probably were later evolutionary developments; that is, at no single time was the code immutably fixed, although massive changes were not tolerated once a general code began to function early in evolution.

The Folded Structure of tRNA Promotes Its Decoding Functions

Translation, or decoding, of the four-nucleotide language of DNA and mRNA into the 20-amino acid language of proteins requires tRNAs and enzymes called *aminoacyl-tRNA synthetases*. To participate in protein synthesis, a tRNA molecule must become chemically linked to a particular amino acid via a high-energy bond, forming an *aminoacyl-tRNA* (Figure 4-19). The anticodon in the tRNA then base-pairs with a codon in mRNA so that the activated amino acid can be added to the growing polypeptide chain (see Figure 4-17).

Some 30–40 different tRNAs have been identified in bacterial cells and as many as 50–100 in animal and plant cells. Thus the number of tRNAs in most cells is more than the number of amino acids used in protein synthesis (20) and also differs from the number of amino acid codons in the genetic code (61). Consequently, many amino acids have more than one tRNA to which they can attach (explaining how there can be more tRNAs than amino acids); in addition, many tRNAs can pair with more than one codon (explaining how there can be more codons than tRNAs).

The function of tRNA molecules, which are 70–80 nucleotides long, depends on their precise three-dimensional structures. In solution, all tRNA molecules fold into a similar stem-loop arrangement that resembles a cloverleaf when drawn in two dimensions (Figure 4-20a). The four stems are short double helices stabilized by Watson-Crick base pairing; three of the four stems have loops containing seven or eight bases at their ends, while the remaining, unlooped stem contains the free 3' and 5' ends of the chain. The three nucleotides composing the anticodon are located at the center of the middle loop, in an accessible position that facilitates codon-anticodon base pairing. In all tRNAs, the 3' end of the unlooped amino acid *acceptor stem* has the sequence CCA, which in most cases is added after synthesis and processing of the tRNA are complete. Several bases in most tRNAs also are modified after transcription, creating non-standard nucleotides such as inosine, dihydrouridine, and pseudouridine. As we will see shortly, some of these modified bases are known to play an important role in protein

TABLE 4-2 Known Deviations from the Universal Genetic Code

Codon	Universal Code	Unusual Code*	Occurrence
UGA	Stop	Trp	<i>Mycoplasma</i> , <i>Spiroplasma</i> , mitochondria of many species
CUG	Leu	Thr	Mitochondria in yeasts
UAA, UAG	Stop	Gln	<i>Acetabularia</i> , <i>Tetrahymena</i> , <i>Paramecium</i> . etc.
UGA	Stop	Cys	<i>Euplotes</i>

FIGURE 4-19 Decoding nucleic acid sequence into amino acid sequence. The process for translating nucleic acid sequences in mRNA into amino acid sequences in proteins involves two steps. Step **1**: An aminoacyl-tRNA synthetase first couples a specific amino acid, via a high-energy ester bond (yellow), to either the 2' or 3' hydroxyl of the

terminal adenosine in the corresponding tRNA. Step **2**: A three-base sequence in the tRNA (the anticodon) then base-pairs with a codon in the mRNA specifying the attached amino acid. If an error occurs in either step, the wrong amino acid may be incorporated into a polypeptide chain. Phe = phenylalanine.

synthesis. Viewed in three dimensions, the folded tRNA molecule has an L shape with the anticodon loop and acceptor stem forming the ends of the two arms (Figure 4-20b).

Nonstandard Base Pairing Often Occurs Between Codons and Anticodons

If perfect Watson-Crick base pairing were demanded between codons and anticodons, cells would have to contain at least 61 different types of tRNAs, one for each codon that specifies an amino acid. As noted above, however, many cells contain fewer than 61 tRNAs. The explanation for the smaller number lies in the capability of a single tRNA anticodon to recognize more than one, but not necessarily every, codon corresponding to a given amino acid. This broader recognition can occur because of nonstandard pairing between bases in the so-called *wobble* position: that is, the third (3') base in an mRNA codon and the corresponding first (5') base in its tRNA anticodon.

The first and second bases of a codon almost always form standard Watson-Crick base pairs with the third and second bases, respectively, of the corresponding anticodon, but four nonstandard interactions can occur between bases in the wobble position. Particularly important is the G·U base pair,

FIGURE 4-20 Structure of tRNAs. (a) Although the exact nucleotide sequence varies among tRNAs, they all fold into four base-paired stems and three loops. The CCA sequence at the 3' end also is found in all tRNAs. Attachment of an amino acid to the 3' A yields an aminoacyl-tRNA. Some of the A, C, G, and U residues are modified post-transcriptionally in most tRNAs (see key). Dihydrouridine (D) is nearly always present in the D loop; likewise, ribothymidine (T) and pseudouridine (Ψ) are almost always present in the TΨCG loop. Yeast alanine tRNA, represented here, also contains other modified bases. The triplet at the tip of the anticodon loop base-pairs with the corresponding codon in mRNA. (b) Three-dimensional model of the generalized backbone of all tRNAs. Note the L shape of the molecule. [Part (a) see R. W. Holly et al., 1965, *Science* **147**:1462. Part (b) adapted from J. G. Arnez and D. Moras, 1997, *Trends Biochem. Sci.* **22**:211.]

FIGURE 4-21 Nonstandard base pairing at the wobble position.

The base in the third (or wobble) position of an mRNA codon often forms a nonstandard base pair with the base in the first (or wobble) position of a tRNA anticodon. Wobble pairing allows a tRNA to recognize more than one mRNA codon (top); conversely, it allows a codon to be recognized by more than one kind of tRNA (bottom), although each tRNA will bear the same amino acid. Note that a tRNA with I (inosine) in the wobble position can "read" (become paired with) three different codons, and a tRNA with G or U in the wobble position can read two codons. Although A is theoretically possible in the wobble position of the anticodon, it is almost never found in nature.

which structurally fits almost as well as the standard G-C pair. Thus, a given anticodon in tRNA with G in the first (wobble) position can base-pair with the two corresponding codons that have either pyrimidine (C or U) in the third position (Figure 4-21). For example, the phenylalanine codons UUU and UUC (5'→3') are both recognized by the tRNA that has GAA (5'→3') as the anticodon. In fact, any two codons of the type NN_P (N = any base; _P = pyrimidine) encode a single amino acid and are decoded by a single tRNA with G in the first (wobble) position of the anticodon.

Although adenine rarely is found in the anticodon wobble position, many tRNAs in plants and animals contain inosine (I), a deaminated product of adenine, at this position. Inosine can form nonstandard base pairs with A, C, and U. A tRNA with inosine in the wobble position thus can recognize the corresponding mRNA codons with A, C, or U in the third (wobble) position (see Figure 4-21). For this reason, inosine-containing tRNAs are heavily employed in translation of the synonymous codons that specify a single amino

acid. For example, four of the six codons for leucine (CUA, CUC, CUU, and UUA) are all recognized by the same tRNA with the anticodon 3'-GAI-5'; the inosine in the wobble position forms nonstandard base pairs with the third base in the four codons. In the case of the UUA codon, a nonstandard G-U pair also forms between position 3 of the anticodon and position 1 of the codon.

Amino Acids Become Activated When Covalently Linked to tRNAs

Recognition of the codon or codons specifying a given amino acid by a particular tRNA is actually the second step in decoding the genetic message. The first step, attachment of the appropriate amino acid to a tRNA, is catalyzed by a specific *aminoacyl-tRNA synthetase*. Each of the 20 different synthetases recognizes *one* amino acid and *all* its compatible, or *cognate*, tRNAs. These coupling enzymes link an amino acid to the free 2' or 3' hydroxyl of the adenosine at the 3' terminus of tRNA molecules by an ATP-requiring reaction. In this reaction, the amino acid is linked to the tRNA by a high-energy bond and thus is said to be *activated*. The energy of this bond subsequently drives formation of the peptide bonds linking adjacent amino acids in a growing polypeptide chain. The equilibrium of the aminoacylation reaction is driven further toward activation of the amino acid by hydrolysis of the high-energy phosphoanhydride bond in the released pyrophosphate (see Figure 4-19).

Aminoacyl-tRNA synthetases recognize their cognate tRNAs by interacting primarily with the anticodon loop and acceptor stem, although interactions with other regions of a tRNA also contribute to recognition in some cases. Also, specific bases in incorrect tRNAs that are structurally similar to a cognate tRNA will inhibit charging of the incorrect tRNA. Thus, recognition of the correct tRNA depends on both positive interactions and the absence of negative interactions. Still, because some amino acids are so similar structurally, aminoacyl-tRNA synthetases sometimes make mistakes. These are corrected, however, by the enzymes themselves, which have a *proofreading* activity that checks the fit in their amino acid-binding pocket. If the wrong amino acid becomes attached to a tRNA, the bound synthetase catalyzes removal of the amino acid from the tRNA. This crucial function helps guarantee that a tRNA delivers the correct amino acid to the protein-synthesizing machinery. The overall error rate for translation in *E. coli* is very low, approximately 1 per 50,000 codons, evidence of both the fidelity of tRNA recognition and the importance of proofreading by aminoacyl-tRNA synthetases.

KEY CONCEPTS of Section 4.3

The Decoding of mRNA by tRNAs

- Genetic information is transcribed from DNA into mRNA in the form of an overlapping, degenerate triplet code.
- Each amino acid is encoded by one or more three-nucleotide sequences (codons) in mRNA. Each codon specifies one amino

acid, but most amino acids are encoded by multiple codons (see Table 4-1).

- The AUG codon for methionine is the most common start codon, specifying the amino acid at the NH₂-terminus of a protein chain. Three codons (UAA, UAG, UGA) function as stop codons and specify no amino acids.
- A reading frame, the uninterrupted sequence of codons in mRNA from a specific start codon to a stop codon, is translated into the linear sequence of amino acids in a polypeptide chain.
- Decoding of the nucleotide sequence in mRNA into the amino acid sequence of proteins depends on tRNAs and aminoacyl-tRNA synthetases.
- All tRNAs have a similar three-dimensional structure that includes an acceptor arm for attachment of a specific amino acid and a stem-loop with a three-base anticodon sequence at its ends (see Figure 4-20). The anticodon can base-pair with its corresponding codon in mRNA.
- Because of nonstandard interactions, a tRNA may base-pair with more than one mRNA codon; conversely, a particular codon may base-pair with multiple tRNAs. In each case, however, only the proper amino acid is inserted into a growing polypeptide chain.
- Each of the 20 aminoacyl-tRNA synthetases recognizes a single amino acid and covalently links it to a cognate tRNA, forming an aminoacyl-tRNA (see Figure 4-19). This reaction activates the amino acid, so it can participate in peptide bond formation.

4.4 Stepwise Synthesis of Proteins on Ribosomes

The previous sections have introduced two of the major participants in protein synthesis—mRNA and aminoacylated tRNA. Here we first describe the third key player in protein synthesis—the rRNA-containing ribosome—before taking a detailed look at how all three components are brought together to carry out the biochemical events leading to formation of polypeptide chains on ribosomes. Similar to transcription, the complex process of translation can be divided into three stages—initiation, elongation, and termination—which we consider in order. We focus our description on translation in eukaryotic cells, but the mechanism of translation is fundamentally the same in all cells.

Ribosomes are Protein-Synthesizing Machines

If the many components that participate in translating mRNA had to interact in free solution, the likelihood of simultaneous collisions occurring would be so low that the rate of

amino acid polymerization would be very slow. The efficiency of translation is greatly increased by the binding of the mRNA and the individual aminoacyl-tRNAs within a ribosome. The ribosome, the most abundant RNA-protein complex in the cell, directs elongation of a polypeptide at a rate of three to five amino acids added per second. Small proteins of 100–200 amino acids are therefore made in a minute or less. On the other hand, it takes 2–3 hours to make the largest known protein, titin, which is found in muscle and contains about 30,000 amino acid residues. The cellular machine that accomplishes this task must be precise and persistent.

With the aid of the electron microscope, ribosomes were first discovered as small, discrete, RNA-rich particles in cells that secrete large amounts of protein. However, their role in protein synthesis was not recognized until reasonably pure ribosome preparations were obtained. In vitro radiolabeling experiments with such preparations showed that radioactive amino acids were first incorporated into growing polypeptide chains that were associated with ribosomes before appearing in finished chains.

Though there are differences between the ribosomes of prokaryotes and eukaryotes, the great structural and functional similarities between ribosomes from all species reflects the common evolutionary origin of the most basic constituents of living cells. A ribosome is composed of three (in bacteria) or four (in eukaryotes) different rRNA molecules and as many as 83 proteins, organized into a large subunit and a small subunit (Figure 4-22). The ribosomal subunits and the rRNA molecules are commonly designated in Svedberg units (S), a measure of the sedimentation rate of macromolecules centrifuged under standard conditions—essentially, a measure of size. The small ribosomal subunit contains a single rRNA molecule, referred to as *small rRNA*. The large subunit contains a molecule of *large rRNA* and one molecule of 5S rRNA, plus an additional molecule of 5.8S rRNA in vertebrates. The lengths of the rRNA molecules, the quantity of proteins in each subunit, and consequently the sizes of the subunits differ between bacterial and eukaryotic cells. The assembled ribosome is 70S in bacteria and 80S in vertebrates.

The sequences of the small and large rRNAs from several thousand organisms are now known. Although the primary nucleotide sequences of these rRNAs vary considerably, the same parts of each type of rRNA theoretically can form base-paired stem-loops, which would generate a similar three-dimensional structure for each rRNA in all organisms. The three-dimensional structures of bacterial rRNAs have been determined by x-ray crystallography of isolated 50S and 30S subunits and entire 70S ribosomes (Figure 4-23). The multiple, much smaller ribosomal proteins for the most part are associated with the surface of the rRNAs. Although the number of protein molecules in ribosomes greatly exceeds the number of RNA molecules, RNA constitutes about 60 percent of the mass of a ribosome. The sites where tRNAs are bound by ribosomes are known as the *A site*, the *P site*, and the *E site*. As we will see shortly, tRNAs move between these sites as protein synthesis takes place. Crystal structures of the yeast 80S ribosome, a protozoan 40S subunit, as well

FIGURE 4-22 Prokaryotic and eukaryotic ribosome components.

In all cells, each ribosome consists of a large and a small subunit. The two subunits contain rRNAs (red) of different lengths, as well as a different set of proteins. All ribosomes contain two major rRNA

molecules (23S and 16S rRNA in bacteria; 28S and 18S rRNA in vertebrates) and a 5S rRNA. The large subunit of vertebrate ribosomes also contains a 5.8S rRNA base-paired to the 28S rRNA. The number of ribonucleotides (rNTs) in each rRNA type is indicated.

as cryo-electron microscopy of plant ribosomes have been reported recently. They are generally similar to bacterial ribosomes but are about 50 percent larger because of eukaryotic-specific insertions of RNA segments into regions of the bacterial rRNAs as well as the presence of a larger number of proteins (see Figure 4-22). Basic aspects of protein synthesis are thought to be similar, although initiation of translation in eukaryotes, discussed later, is more complex and subject to additional mechanisms of regulation.

During translation, a ribosome moves along an mRNA chain, interacting with various protein factors and tRNAs and undergoing large conformational changes. Despite the complexity of the ribosome, great progress has been made in determining the overall structure of bacterial ribosomes and how they function in protein synthesis. More than 50 years after the initial discovery of ribosomes, their overall structure and function during protein synthesis are finally becoming clear.

Methionyl-tRNA^{Met} Recognizes the AUG Start Codon

As noted earlier, the AUG codon for methionine functions as the start codon in the vast majority of mRNAs. A critical aspect of translation initiation is to begin protein synthesis at the start codon, thereby establishing the correct reading

frame for the entire mRNA. Both prokaryotes and eukaryotes contain two different methionine tRNAs: tRNA^{Met}_i can initiate protein synthesis, and tRNA^{Met}_e can incorporate methionine only into a growing protein chain. The same aminoacyl-tRNA synthetase (MetRS) charges both tRNAs with methionine. But *only* Met-tRNA^{Met}_i (i.e., activated methionine attached to tRNA^{Met}_i) can bind at the appropriate site on the small ribosomal subunit, the *P site*, to begin synthesis of a polypeptide chain. The regular Met-tRNA^{Met}_e and all other charged tRNAs bind only to the *A site*, as described later. tRNAs enter the exit or *E site* after transferring their covalently bound amino acid to the growing polypeptide chain.

Eukaryotic Translation Initiation Usually Occurs at the First AUG Closest to the 5' End of an mRNA

During the first stage of translation, the small and large ribosomal subunits assemble around an mRNA that has an activated initiator tRNA correctly positioned at the start codon in the ribosomal P site. In eukaryotes, this process is mediated by a special set of proteins known as **eukaryotic translation initiation factors (eIFs)**. As each individual component joins the complex, it is guided by interactions with specific eIFs. Several of these initiation factors bind GTP, and the hydrolysis

FIGURE 4-23 Structure of *E. coli* 70S ribosome as determined by x-ray crystallography. Model of the ribosome viewed along the interface between the large (50S) and small (30S) subunits. The 16S rRNA and proteins in the small subunit are colored light green and dark green, respectively; the 23S rRNA and proteins in the large subunit are

colored light purple and dark purple, respectively; and the 5S rRNA is colored dark blue. The positions of the ribosomal A, P, and E sites are indicated. Note that the ribosomal proteins are located primarily on the surface of the ribosome, and the rRNAs on the inside, lining the A, P, and E sites. [From B. S. Schuwirth et al., 2005, *Science* **310**:827.]

of GTP to GDP functions as a proofreading switch that only allows subsequent steps to proceed if the preceding step has occurred correctly. Before GTP hydrolysis, the complex is unstable, allowing a second attempt at complex formation until the correct complex assembles, resulting in GTP hydrolysis and stabilization of the appropriate complex. Considerable

progress has been made in the past few years in understanding translation initiation in vertebrates.

The current model for initiation of translation in vertebrates is depicted in Figure 4-24. Large and small ribosomal subunits released from a previous round of translation are kept apart by the binding of eIFs 1, 1A, and 3 to the small

40S subunit (Figure 4-24, *top*). The first step of translation initiation is formation of a *43S preinitiation complex*. This preinitiation complex is formed when the 40S subunit with eIFs 1, 1A, and 3 associates with eIF5 and a ternary complex consisting of the Met-tRNA_i^{Met} and eIF2 bound to GTP (Figure 4-24, steps **1** and **3**). The initiation factor eIF2 alternates between association with GTP and GDP; it can only bind Met-tRNA_i^{Met} when it is associated with GTP. Cells can regulate protein synthesis by phosphorylating a serine residue on the eIF2 bound to GDP; the phosphorylated complex is unable to exchange the bound GDP for GTP and cannot bind Met-tRNA_i^{Met}, thus inhibiting protein synthesis.

The mRNA to be translated is bound by the multiple-subunit eIF4 complex, which interacts with both the 5'-cap structure and the poly(A)-binding protein (PABP) bound in multiple copies to the mRNA poly(A) tail. Both interactions are required for translation of most mRNAs. This results in formation of a circular complex (Figure 4-24, step **3**). The eIF4 cap-binding complex consists of several subunits with different functions. The eIF4E subunit binds the 5'-cap structure on mRNAs (Figure 4-14). The large eIF4G subunit interacts with PABP bound to the mRNA poly(A) tail, and also forms a scaffold to which the other eIF4 subunits bind. The mRNA-eIF4 complex then associates with the preinitiation complex through an interaction between eIF4G and eIF3 (step **4**).

The initiation complex then slides along, or *scans*, the associated mRNA as the helicase activity of eIF4A, stimulated by eIF4B, uses energy from ATP hydrolysis to unwind RNA secondary structure (step **5**). Scanning stops when the tRNA_i^{Met} anticodon recognizes the start codon, which is the first AUG downstream from the 5' end in most eukaryotic mRNAs. Recognition of the start codon leads to hydrolysis of the GTP associated with eIF2, an irreversible step that prevents further scanning, resulting in formation of the *48S initiation complex* (step **6**). This commitment to the correct initiation codon is facilitated by eIF5, an eIF2 GTPase-activating protein (GAP, see Figure 3-32). Selection of the initiating AUG is facilitated by specific surrounding nucleotides called the *Kozak sequence*, for Marilyn Kozak, who defined it: (5') **ACCAUGG** (3'). The A preceding the AUG (in bold) and the G immediately following it are the most important nucleotides affecting translation initiation efficiency.

Association of the large (60S) subunit is mediated by eIF5B bound to GTP, and results in displacement of many of the initiation factors (step **7**). Correct association between the ribosomal subunits results in hydrolysis of the eIF5B-bound GTP to GDP and release of eIF5B-GDP and eIF1A (step **8**), completing formation of an *80S initiation complex*. Coupling the ribosome subunit joining reaction to GTP hydrolysis by eIF5B allows the initiation process to continue only when the subunit interaction has occurred correctly. It also makes this an irreversible step, so that the ribosomal subunits do not dissociate until the entire mRNA is translated and protein synthesis is terminated.

The eukaryotic protein-synthesizing machinery begins translation of most cellular mRNAs within about 100 nucleotides of the 5'-capped end as just described. However, some

cellular mRNAs contain an internal ribosome entry site (IRES) located far downstream of the 5' end. It is thought that cellular IRESs form RNA structures that interact with a complex of eIF4A and eIF4G that then associates with eIF3 bound to 40S subunits with eIF1 and eIF1A. This assembly then binds an eIF2 ternary complex to assemble an initiation complex directly on a neighboring AUG codon. In addition, translation of some positive-stranded viral RNAs, which lack a 5' cap, is initiated at viral IRES sequences. These fall into different classes depending on how many of the standard eIFs are required for initiation. In the case of cricket paralysis virus, the ≈200-nt-long IRES folds into a complex structure that interacts directly with the 40S ribosome and leads to initiation without any of the eIFs or even the initiator Met-tRNA_i^{Met}.

In bacteria, binding of the small ribosomal subunit to an initiation site occurs by a different mechanism that allows initiation at internal sites in the polycistronic mRNAs transcribed from operons. In bacterial mRNAs, an ≈6-base sequence complementary to the 3' end of the small rRNA precedes the AUG start codon by 4–7 nucleotides. Base pairing between this sequence in the mRNA, called the Shine-Dalgarno sequence after its discoverers, and the small rRNA places the small ribosomal subunit in the proper position for initiation. Initiation factors comparable to eIF1A, eIF2, eIF3, and f-Met-tRNA_i^{Met} then associate with the small subunit, followed by association of the large subunit to form the complete bacterial ribosome.

During Chain Elongation Each Incoming Aminoacyl-tRNA Moves Through Three Ribosomal Sites

The correctly positioned ribosome–Met-tRNA_i^{Met} complex is now ready to begin the task of stepwise addition of amino acids by the in-frame translation of the mRNA. As is the case with initiation, a set of special proteins, termed **translation elongation factors (EFs)**, are required to carry out this process of chain elongation. The key steps in elongation are entry of each succeeding aminoacyl-tRNA with a tRNA complementary to the next codon, formation of a peptide bond, and the movement, or *translocation*, of the ribosome one codon at a time along the mRNA.

At the completion of translation initiation, as noted already, Met-tRNA_i^{Met} is bound to the P site on the assembled 80S ribosome (Figure 4-25, *top*). This region of the ribosome is called the *P* site because the tRNA chemically linked to the growing polypeptide chain is located here. The second aminoacyl-tRNA is brought into the ribosome as a ternary complex in association with EF1α·GTP and becomes bound to the *A* site, so named because it is where aminoacylated tRNAs bind (step **3**). EF1α·GTP bound to various aminoacyl-tRNAs diffuse into the *A* site, but the next step in translation proceeds only when the tRNA anticodon base-pairs with the second codon in the coding region. When that occurs properly, the GTP in the associated EF1α·GTP is hydrolyzed. The hydrolysis of GTP promotes a conformational change in

FIGURE 4-25 Peptidyl chain elongation in eukaryotes. Once the 80S ribosome with Met-tRNA^{Met} in the ribosome P site is assembled (top), a ternary complex bearing the second amino acid (aa₂) coded by the mRNA binds to the A site (step 1). Following a conformational change in the ribosome induced by hydrolysis of GTP in EF1α·GTP (step 2), the large rRNA catalyzes peptide bond formation between Met and aa₂ (step 3). Hydrolysis of GTP in EF2·GTP causes another conformational change in the ribosome that results in its translocation one codon along the mRNA and shifts the unacylated tRNA^{Met} to the E site and the tRNA with the bound peptide to the P site (step 4). The cycle can begin again with binding of a ternary complex bearing aa₃ to the now open A site. In the second and subsequent elongation cycles, the tRNA at the E site is ejected during step 2 as a result of the conformational change induced by hydrolysis of GTP in EF1α·GTP. [Adapted from K. H. Nierhaus et al., 2000, in R. A. Garrett et al., eds., *The Ribosome: Structure, Function, Antibiotics, and Cellular Interactions*, ASM Press, p. 319.]

EF1α that leads to release of the resulting EF1α·GDP complex and tight binding of the aminoacyl-tRNA in the A site (step 2). This conformational change also positions the aminoacylated 3' end of the tRNA in the A site in close proximity to the 3' end of the Met-tRNA^{Met} in the P site. GTP hydrolysis, and hence tight binding, does not occur if the anticodon of the incoming aminoacyl-tRNA cannot base-pair with the codon at the A site. In this case, the ternary complex diffuses away, leaving an empty A site that can associate with other aminoacyl-tRNA–EF1α·GTP complexes until a correctly base-paired tRNA is bound. Thus, GTP hydrolysis by EF1α is another proofreading step that allows protein synthesis to proceed only when the correct aminoacylated tRNA is bound to the A site. This phenomenon contributes to the fidelity of protein synthesis.

With the initiating Met-tRNA^{Met} at the P site and the second aminoacyl-tRNA tightly bound at the A site, the α-amino group of the second amino acid reacts with the “activated” (ester-linked) methionine on the initiator tRNA, forming a peptide bond (Figure 4-25, step 3; see Figure 4-17). This *peptidyltransferase reaction* is catalyzed by the large rRNA, which precisely orients the interacting atoms, permitting the reaction to proceed. The 2'-hydroxyl of the terminal A of the peptidyl-tRNA in the P site also participates in catalysis. The catalytic ability of the large rRNA in bacteria has been demonstrated by carefully removing the vast majority of the protein from large ribosomal subunits. The nearly pure bacterial 23S rRNA can catalyze a peptidyltransferase reaction between analogs of aminoacylated-tRNA and peptidyl-tRNA. Further support for the catalytic role of large rRNA in protein synthesis came from high-resolution crystallographic studies showing that no proteins lie near the site of peptide bond synthesis in the crystal structure of the bacterial large subunit.

Following peptide bond synthesis, the ribosome translocates along the mRNA a distance equal to one codon. This translocation step is monitored by hydrolysis of the GTP in

eukaryotic EF2·GTP. Once translocation has occurred correctly, the bound GTP is hydrolyzed, another irreversible process that prevents the ribosome from moving along the RNA in the wrong direction or from translocating an incorrect number of nucleotides. As a result of conformational changes

in the ribosome that accompany proper translocation and the resulting GTP hydrolysis by EF2, tRNA^{Met}, now without its activated methionine, is moved to the *E* (exit) site on the ribosome; concurrently, the second tRNA, now covalently bound to a dipeptide (a peptidyl-tRNA), is moved to the P site (Figure 4-25, step 4). Translocation thus returns the ribosome conformation to a state in which the A site is open and able to accept another aminoacylated tRNA complexed with EF1α·GTP, beginning another cycle of chain elongation.

Repetition of the elongation cycle depicted in Figure 4-25 adds amino acids one at a time to the C-terminus of the growing polypeptide as directed by the mRNA sequence, until a stop codon is encountered. In subsequent cycles, the conformational change that occurs in step 2 ejects the unacylated tRNA from the E site. As the nascent polypeptide chain becomes longer, it threads through a channel in the large ribosomal subunit, exiting at a position opposite the side that interacts with the small subunit (Figure 4-26).

In the absence of the ribosome, the three-base-pair RNA-RNA hybrid between the tRNA anticodons and the mRNA codons in the A and P sites would not be stable; RNA-RNA duplexes between separate RNA molecules must be considerably longer to be stable under physiological conditions. However, multiple interactions between the large and small rRNAs and general domains of tRNAs (e.g., the D and TΨCG loops, see Figure 4-20) stabilize the tRNAs in the A and P sites, while other RNA-RNA interactions sense correct codon-anticodon base pairing, assuring that the genetic code is read properly. Then, interactions between rRNAs and the general domains of all tRNAs result in the movement of the

tRNAs between the A, P, and E sites as the ribosome translocates along the mRNA one three-nucleotide codon at a time.

Translation Is Terminated by Release Factors When a Stop Codon Is Reached

The final stages of translation, like initiation and elongation, require highly specific molecular signals that decide the fate of the mRNA-ribosome-tRNA-peptidyl complex. Two types of specific protein release factors (RFs) have been discovered. Eukaryotic eRF1, whose shape is similar to that of tRNAs, acts by binding to the ribosomal A site and recognizing stop codons directly. Like some of the initiation and elongation factors discussed previously, the second eukaryotic release factor, eRF3, is a GTP-binding protein. The eRF3·GTP acts in concert with eRF1 to promote cleavage of the peptidyl-tRNA, thus releasing the completed protein chain (Figure 4-27). Bacteria have two release factors (RF1 and RF2) that are functionally analogous to eRF1 and a GTP-binding factor (RF3) that is analogous to eRF3. Once again, the eRF3 GTPase monitors the correct recognition of a stop codon by eRF1. The peptidyl-tRNA bond of the tRNA in the P site is not cleaved, terminating translation, until one of the three stop codons is correctly recognized by eRF1, another example of a proofreading step in protein synthesis.

Release of the completed protein leaves a free tRNA in the P site and the mRNA still associated with the 80S ribosome with eRF1 and eRF3-GDP bound in the A site. In eukaryotes, ribosome recycling occurs when this post-termination complex is bound by a protein called ABCE1, which uses energy from ATP hydrolysis to separate the subunits and release the mRNA. Initiation factors eIF1, eIF1A, and eIF3 are also required and load onto the 40S subunit, making it ready for another round of initiation (Figure 4-24, *top*). In reality, a free mRNA is never released as diagrammed in Figure 4-27 for simplicity. Rather, the mRNA has other ribosomes associated with it in various stages of elongation, PABP bound to the polyA tail, and eIF4 complex associated with the 5'-cap, ready to associate with another 43S preinitiation complex (Figure 4-24).

FIGURE 4-26 Model of *E. coli* 70S ribosome bound to an mRNA with a nascent polypeptide chain in the exit tunnel. The model is based on cryo-EM studies. Three tRNAs are superimposed on the A (pink), P (green), and E (yellow) sites. The nascent polypeptide chain is buried in a tunnel in the large ribosomal subunit that begins close to the acceptor stem of the tRNA in the P site. [See I. S. Gabashvili et al., 2000, *Cell* 100:537; courtesy of J. Frank.]

Polysomes and Rapid Ribosome Recycling Increase the Efficiency of Translation

Translation of a single eukaryotic mRNA molecule to yield a typical-sized protein takes one to two minutes. Two phenomena significantly increase the overall rate at which cells can synthesize a protein: the simultaneous translation of a single mRNA molecule by multiple ribosomes, and rapid recycling of ribosomal subunits after they disengage from the 3' end of an mRNA. Simultaneous translation of an mRNA by multiple ribosomes is readily observable in electron micrographs and by sedimentation analysis, revealing mRNA attached to multiple ribosomes bearing nascent growing polypeptide chains. These structures, referred to as **polysomes** or **polysomes**, were seen to be circular in electron micrographs of some tissues. Subsequent studies with purified initiation factors explained

FIGURE 4-27 Termination of translation in eukaryotes. When a ribosome bearing a nascent protein chain reaches a stop codon (UAA, UGA, UAG), release factor eRF1 enters the A site together with eRF3-GTP. Hydrolysis of the bound GTP is accompanied by cleavage of the peptide chain from the tRNA in the P site and ejection of the tRNA in the E site, forming a post-termination complex. The ribosomal subunits are separated by the action of the ABCE1 ATPase together with eIF1, eIF1A, and eIF3. The 40S subunit is released bound to these eIFs, ready to initiate another cycle of translation (see Figure 4-24).

the circular shape of polyribosomes and suggested the mechanism by which ribosomes recycle efficiently.

These studies revealed that multiple copies of the poly(A)-binding protein (PABP) interact with both an mRNA poly(A)

tail and the eIF4G subunit of eIF4. Since the eIF4E subunit of eIF4 binds to the cap structure on the 5' end of an mRNA, the two ends of an mRNA molecule are bridged by the intervening proteins, forming a "circular" mRNA (Figure 4-28a). Because the two ends of a polysome are relatively close together, ribosomal subunits that disengage from the 3' end are positioned near the 5' end, facilitating re-initiation by the interaction of the 40S subunit and its associated initiation factors with eIF4 bound to the 5' cap. The circular pathway depicted in Figure 4-28b is thought to enhance ribosome recycling and thus increase the efficiency of protein synthesis.

GTPase-Superfamily Proteins Function in Several Quality Control Steps of Translation

We can now see that one or more GTP-binding proteins participate in each stage of translation. These proteins belong to the GTPase superfamily of switch proteins that cycle between a GTP-bound active form and GDP-bound inactive form (see Figure 3-32). Hydrolysis of the bound GTP causes a conformational change in the GTPase itself and other associated proteins that are critical to various complex molecular processes. In translation initiation, for instance, hydrolysis of eIF2-GTP to eIF2-GDP prevents further scanning of the mRNA once the start site is encountered and allows binding of the large ribosomal subunit to the small subunit (see Figure 4-24, step 6). Similarly, hydrolysis of EF1α-GTP to EF1α-GDP during chain elongation occurs only when the A site is occupied by a charged tRNA with an anticodon that base-pairs with the codon in the A site. GTP hydrolysis causes a conformational change in EF1α resulting in release of its bound tRNA, allowing the aminoacylated 3' end of the charged tRNA to move into the position required for peptide bond formation (Figure 4-26, step 3). Hydrolysis of EF2-GTP to EF2-GDP leads to correct translocation of the ribosome along the mRNA, (see Figure 4-26, step 4), and hydrolysis of eRF3-GTP to eRF3-GDP assures correct termination of translation (Figure 4-27). Since hydrolysis of the high energy β-γ phosphodiester bond of GTP is irreversible, coupling of these steps in protein synthesis to GTP hydrolysis prevents them from going in the reverse direction.

Nonsense Mutations Cause Premature Termination of Protein Synthesis

One kind of mutation that can inactivate a gene in any organism is a base-pair change that converts a codon normally encoding an amino acid into a stop codon, e.g., UAC (encoding tyrosine) → UAG (stop). When this occurs early in the reading frame, the resulting truncated protein usually is nonfunctional. Such mutations are called *nonsense* mutations because when the genetic code equating each triplet codon sequence with a single amino acid was being deciphered by researchers, the three stop codons were found to not encode any amino acid—they did not "make sense."

In genetic studies with the bacterium *E. coli*, it was discovered that the effect of a nonsense mutation can be suppressed

EXPERIMENTAL FIGURE 4-28 Circular structure of mRNA increases translation efficiency. Eukaryotic mRNA forms a circular structure owing to interactions of three proteins. (a) In the presence of purified poly(A)-binding protein (PABP), eIF4E, and eIF4G, eukaryotic mRNAs form circular structures, visible in this force-field electron micrograph. In these structures, protein-protein and protein-mRNA interactions form a bridge between the 5' and 3' ends of the mRNA. (b) Model of protein synthesis on circular polysomes and recycling of ribosomal subunits. Multiple individual ribosomes can simultaneously translate a eukaryotic mRNA, shown here in circular form stabilized by interactions between proteins bound at the 3' and 5' ends. When a ribosome completes translation and dissociates from the 3' end, the separated subunits can rapidly find the nearby 5' cap (m^7G) and PABP-bound poly(A) tail and initiate another round of synthesis. [Part (a) courtesy of A. Sachs.]

by a second mutation in a tRNA gene. This occurs when the sequence encoding the anticodon in the tRNA gene is changed to a triplet that is complementary to the original stop codon, e.g., a mutation in tRNA^{Tyr} that changes its anticodon from GUA to CUA, which can base-pair with the UAG stop codon. The mutant tRNA can still be recognized by the tyrosine amino acyl synthetase and coupled to tyrosine. Cells with

both the original nonsense mutation and the second mutation in the anticodon of the tRNA^{Tyr} gene consequently can insert a tyrosine at the position of the mutant stop codon, allowing protein synthesis to continue past the original nonsense mutation. This mechanism of suppression is not highly efficient, so translation of normal mRNAs with a UAG stop codon terminates at the normal position in most instances. If enough of the protein encoded by the original gene with the nonsense mutation is produced to provide its essential functions, the effect of the first mutation is said to be *suppressed* by the second mutation in the anticodon of the tRNA gene.

This mechanism of *nonsense suppression* is a powerful tool in genetic studies in bacteria. For example, mutant bacterial viruses can be isolated that cannot grow in normal cells but can grow in cells expressing a nonsense-suppressing tRNA because the mutant virus has a nonsense mutation in an essential gene. Such mutant viruses grown on the nonsense-suppressing cells can then be used in experiments to analyze the function of the mutant gene by infecting normal cells that do not suppress the mutation and analyzing what step in the viral life cycle is defective in the absence of the mutant protein.

KEY CONCEPTS of Section 4.4

Stepwise Synthesis of Proteins on Ribosomes

- Both prokaryotic and eukaryotic ribosomes—the large ribonucleoprotein complexes on which translation occurs—consist of a small and a large subunit (see Figure 4-22). Each subunit contains numerous different proteins and one major rRNA molecule (small or large). The large subunit also contains one accessory 5S rRNA in bacteria and two accessory rRNAs in eukaryotes (5S and 5.8S in vertebrates).
- Analogous rRNAs from many different species fold into quite similar three-dimensional structures containing numerous stem-loops and binding sites for proteins, mRNA, and tRNAs. Much smaller ribosomal proteins are associated with the periphery of the rRNAs.
- Of the two methionine tRNAs found in all cells, only one (tRNA_{Met}^{Met}) functions in initiation of translation.
- Each stage of translation—initiation, chain elongation, and termination—requires specific protein factors including GTP-binding proteins that hydrolyze their bound GTP to GDP when a step has been completed successfully.
- During initiation, the ribosomal subunits assemble near the translation start site in an mRNA molecule with the tRNA carrying the amino-terminal methionine (Met-tRNA_{Met}^{Met}) base-paired with the start codon (Figure 4-24).
- Chain elongation entails a repetitive four-step cycle: loose binding of an incoming aminoacyl-tRNA to the A site on the ribosome; tight binding of the correct aminoacyl-tRNA to the A site accompanied by release of the previously used tRNA from the E site; transfer of the growing peptidyl chain to the incoming amino acid catalyzed by large rRNA; and

translocation of the ribosome to the next codon, thereby moving the peptidyl-tRNA in the A site to the P site and the now unacylated tRNA in the P site to the E site (see Figure 4-25).

- In each cycle of chain elongation, the ribosome undergoes two conformational changes monitored by GTP-binding proteins. The first (EF1 α) permits tight binding of the incoming aminoacyl-tRNA to the A site and ejection of a tRNA from the E site, and the second (EF2) leads to translocation.
- Termination of translation is carried out by two types of termination factors: those that recognize stop codons and those that promote hydrolysis of peptidyl-tRNA (see Figure 4-27). Once again, correct recognition of a stop codon is monitored by a GTPase (eRF3).
- The efficiency of protein synthesis is increased by the simultaneous translation of a single mRNA by multiple ribosomes, forming a polyribosome, or simply polysome. In eukaryotic cells, protein-mediated interactions bring the two ends of a polyribosome close together, thereby promoting the rapid recycling of ribosomal subunits, which further increases the efficiency of protein synthesis (see Figure 4-28b).

4.5 DNA Replication

Now that we have seen how genetic information encoded in the nucleotide sequence of DNA is translated into the proteins that perform most cell functions, we can appreciate the necessity for precisely copying DNA sequences during DNA replication, in preparation for cell division (see Figure 4-1, step 4). The regular pairing of bases in the double-helical DNA structure suggested to Watson and Crick that new DNA strands are synthesized by using the existing (*parental*) strands as templates in the formation of new, *daughter* strands complementary to the parental strands.

This base-pairing template model theoretically could proceed either by a *conservative* or a *semiconservative* mechanism. In a conservative mechanism, the two daughter strands would form a new double-stranded (*duplex*) DNA molecule and the parental duplex would remain intact. In a semiconservative mechanism, the parental strands are permanently separated and each forms a duplex molecule with the daughter strand base-paired to it. Definitive evidence that duplex DNA is replicated by a semiconservative mechanism came from a now classic experiment conducted by M. Meselson and W. F. Stahl, outlined in Figure 4-29.

Copying of a DNA template strand into a complementary strand thus is a common feature of DNA replication, transcription of DNA into RNA, and, as we will see later in this chapter, DNA repair and recombination. In all cases, the information in the template in the form of the specific sequence of nucleotides is preserved. In some viruses, single-stranded RNA molecules function as templates for synthesis of complementary RNA or DNA strands. However, the vast preponderance of RNA and DNA in cells is synthesized from preexisting duplex DNA.

DNA Polymerases Require a Primer to Initiate Replication

Analogous to RNA, DNA is synthesized from deoxynucleoside 5'-triphosphate precursors (dNTPs). Also like RNA synthesis, DNA synthesis always proceeds in the 5'→3' direction because chain growth results from formation of a phosphoester bond between the 3' oxygen of a growing strand and the α phosphate of a dNTP (see Figure 4-10a). As discussed earlier, an RNA polymerase can find an appropriate transcription start site on duplex DNA and initiate the synthesis of an RNA complementary to the template DNA strand (see Figure 4-11). In contrast, DNA polymerases cannot initiate chain synthesis *de novo*; instead, they require a short, preexisting RNA or DNA strand, called a **primer**, to begin chain growth. With a primer base-paired to the template strand, a DNA polymerase adds deoxynucleotides to the free hydroxyl group at the 3' end of the primer as directed by the sequence of the template strand:

When RNA is the primer, the daughter strand that is formed is RNA at the 5' end and DNA at the 3' end.

Duplex DNA Is Unwound, and Daughter Strands Are Formed at the DNA Replication Fork

In order for duplex DNA to function as a template during replication, the two intertwined strands must be unwound, or melted, to make the bases available for pairing with the bases of the dNTPs that are polymerized into the newly synthesized daughter strands. This unwinding of the parental DNA strands is by specific **helicases**, beginning at unique segments in a DNA molecule called *replication origins*, or simply *origins*. The nucleotide sequences of origins from different organisms vary greatly, although they usually contain A·T-rich sequences. Once helicases have unwound the parental DNA at an origin, a specialized RNA polymerase called **primase** forms a short RNA primer complementary to the unwound template strands. The primer, still base-paired to its complementary DNA strand, is then elongated by a DNA polymerase, thereby forming a new daughter strand.

The DNA region at which all these proteins come together to carry out synthesis of daughter strands is called the **replication fork**. As replication proceeds, the replication fork and associated proteins move away from the origin. As noted earlier, local unwinding of duplex DNA produces torsional stress, which is relieved by topoisomerase I. In order for DNA polymerases to move along and copy a duplex DNA, helicase must sequentially unwind the duplex and topoisomerase must remove the supercoils that form.

(a) Predicted results

(b) Actual results

EXPERIMENTAL FIGURE 4-29 The Meselson-Stahl experiment.

This experiment showed that DNA replicates by a semiconservative mechanism. *E. coli* cells initially were grown in a medium containing ammonium salts prepared with "heavy" nitrogen (^{15}N) until all the cellular DNA was labeled. After the cells were transferred to a medium containing the normal "light" isotope (^{14}N), samples were removed periodically from the cultures and the DNA in each sample was analyzed by equilibrium density-gradient centrifugation, a procedure that separates macromolecules on the basis of their density. This technique can separate heavy-heavy (H-H), light-light (L-L), and heavy-light (H-L) duplexes into distinct bands. (a) Expected composition of daughter duplex molecules synthesized from ^{15}N -labeled DNA after *E. coli* cells are shifted to ^{14}N -containing medium if DNA replication occurs by a conservative or semiconservative mechanism. Parental heavy (H) strands are in red; light (L) strands synthesized after shift to ^{14}N -containing medium are in blue. Note that the conservative mechanism never generates H-L DNA and that the semiconservative mechanism never generates H-H DNA but does generate H-L DNA during the first and subsequent doublings. With additional replication cycles, the ^{15}N -labeled (H) strands from the original DNA are diluted, so that the vast bulk of the DNA would consist of L-L duplexes

with either mechanism. (b) Actual banding patterns of DNA subjected to equilibrium density-gradient centrifugation before and after shifting ^{15}N -labeled *E. coli* cells to ^{14}N -containing medium. DNA bands were visualized under UV light and photographed. The traces on the left are a measure of the density of the photographic signal, and hence the DNA concentration, along the length of the centrifuge cells from left to right. The number of generations (far left) following the shift to ^{14}N -containing medium was determined by counting the concentration of *E. coli* cells in the culture. This value corresponds to the number of DNA replication cycles that had occurred at the time each sample was taken. After one generation of growth, all the extracted DNA had the density of H-L DNA. After 1.9 generations, approximately half the DNA had the density of H-L DNA; the other half had the density of L-L DNA. With additional generations, a larger and larger fraction of the extracted DNA consisted of L-L duplexes; H-H duplexes never appeared. These results match the predicted pattern for the semiconservative replication mechanism depicted in (a). The bottom two centrifuge cells contained mixtures of H-H DNA and DNA isolated at 1.9 and 4.1 generations in order to clearly show the positions of H-H, H-L, and L-L DNA in the density gradient. [Part (b) from M. Meselson and F. W. Stahl, 1958, *Proc. Nat'l Acad. Sci. USA* **44**:671.]

A major complication in the operation of a DNA replication fork arises from two properties: the two strands of the parental DNA duplex are antiparallel, and DNA polymerases (like RNA polymerases) can add nucleotides to the growing new strands only in the $5'\rightarrow 3'$ direction. Synthesis of one daughter strand, called the **leading strand**, can proceed continuously from a single RNA primer in the $5'\rightarrow 3'$ direction, *the same direction as movement of the replication*

fork (Figure 4-30). The problem comes in synthesis of the other daughter strand, called the **lagging strand**.

Because growth of the lagging strand must occur in the $5'\rightarrow 3'$ direction, copying of its template strand must somehow occur in the *opposite* direction from the movement of the replication fork. A cell accomplishes this feat by synthesizing a new primer every few hundred bases or so on the second parental strand, as more of the strand is exposed by

FIGURE 4-30 Leading-strand and lagging-strand DNA synthesis. Nucleotides are added by a DNA polymerase to each growing daughter strand in the 5'→3' direction (indicated by arrowheads). The leading strand is synthesized continuously from a single RNA primer (red) at its 5' end. The lagging strand is synthesized discontinuously from multiple RNA primers that are formed periodically as each new region of the parental duplex is unwound. Elongation of these primers initially produces Okazaki fragments. As each growing fragment approaches the previous primer, the primer is removed and the fragments are ligated. Repetition of this process eventually results in synthesis of the entire lagging strand.

unwinding. Each of these primers, base-paired to their template strand, is elongated in the 5'→3' direction, forming discontinuous segments called **Okazaki fragments** after their discoverer Reiji Okazaki (see Figure 4-30). The RNA primer of each Okazaki fragment is removed and replaced by DNA chain growth from the neighboring Okazaki fragment; finally, an enzyme called *DNA ligase* joins the adjacent fragments.

Several Proteins Participate in DNA Replication

Detailed understanding of the eukaryotic proteins that participate in DNA replication initially came largely from studies with small viral DNAs, particularly SV40 DNA, the circular genome of a small virus that infects monkeys. Virus-infected cells replicate large numbers of the simple viral genome in a short period of time, making them ideal model systems for studying basic aspects of DNA replication. Because simple viruses like SV40 depend largely on the DNA replication machinery of their host cells (in this case monkey cells), they offer a unique opportunity to study DNA replication of multiple identical small DNA molecules by cellular proteins. Figure 4-31 depicts the multiple proteins that coordinate copying of SV40 DNA at a replication fork. The assembled proteins at a replication fork further illustrate the concept of molecular machines introduced in Chapter 3. These multicomponent complexes permit the cell to carry out an ordered sequence of events that accomplishes essential cell functions.

The molecular machine that replicates SV40 DNA contains only one viral protein. All other proteins involved in SV40 DNA replication are provided by the host cell. This viral protein, *large T-antigen*, forms a hexameric *replicative helicase*, a protein that uses energy from ATP hydrolysis to

unwind the parental strands at a replication fork. Primers for leading and lagging daughter-strand DNA are synthesized by a complex of *primase*, which synthesizes a short RNA primer of ≈10 nucleotides, and *DNA polymerase α* (Pol α), which extends the RNA primer with deoxynucleotides for another ≈20 nucleotides, forming a mixed RNA-DNA primer.

The primer is extended into daughter-strand DNA by *DNA polymerase δ* (Pol δ) and *DNA polymerase ε* (Pol ε), which are less likely to make errors during copying of the template strand than is Pol α because of their proofreading mechanism (see Section 4.7). Recent results indicate that during the replication of cellular DNA, Pol δ synthesizes lagging-strand DNA, while Pol ε synthesizes most of the length of the leading strand. Pol δ and Pol ε each form a complex with *Rfc* (replication factor C) and *PCNA* (proliferating cell nuclear antigen), which displaces the primase-Pol α complex following primer synthesis. As illustrated in Figure 4-31b, PCNA is a homotrimeric protein that has a central hole through which the daughter duplex DNA passes, thereby preventing the PCNA-Rfc-Pol δ and PCNA-Rfc-Pol ε complexes from dissociating from the template. As such, PCNA is known as a *sliding clamp* that enables Pol δ and Pol ε to remain stably associated with a single template strand for thousands of nucleotides. Rfc functions to open the PCNA ring so that it can encircle the short region of double-stranded DNA synthesized by Pol α. Consequently, Rfc is often called a *clamp loader*.

After parental DNA is separated into single-stranded templates at the replication fork, it is bound by multiple copies of RPA (replication protein A), a heterotrimeric protein (Figure 4-31c). Binding of RPA maintains the template in a uniform conformation optimal for copying by DNA polymerases. Bound RPA proteins are dislodged from the parental strands by Pol α, Pol δ, and Pol ε as they synthesize the complementary strands base-paired with the parental strands.

(a) SV40 DNA replication fork

FIGURE 4-31 Model of an SV40 DNA replication fork. (a) A hexamer of large T-antigen (1), a viral protein, functions as a helicase to unwind the parental DNA strands. Single-strand regions of the parental template unwound by large T-antigen are bound by multiple copies of the heterotrimeric protein RPA (2). The leading strand is synthesized by a complex of DNA polymerase ε (Pol ε), PCNA, and Rfc (3). Primers for lagging-strand synthesis (red, RNA; light blue, DNA) are synthesized by a complex of DNA polymerase α (Pol α) and primase (4). The 3' end of each primer synthesized by Pol α-primase is then bound by a PCNA-Rfc-Pol δ complex, which proceeds to extend the primer and synthesize most of each Okazaki fragment (5). (b) The three subunits of PCNA, shown in different colors, form a circular structure with a central hole through which double-stranded DNA passes. A diagram of DNA is shown in the center of a ribbon model of the PCNA trimer. The diagram at the upper left shows the icon

representing PCNA bound to DNA in (a). (c) The large subunit of RPA contains two domains that bind single-stranded DNA. On the left, the structure determined for the two DNA-binding domains of the large subunit bound to single-stranded DNA is shown with the DNA backbone (white backbone with blue bases) parallel to the plane of the page. Note that the single DNA strand is extended with the bases exposed, an optimal conformation for replication by a DNA polymerase. On the right, the view is down the length of the single DNA strand, revealing how RPA β strands wrap around the DNA. The diagram at the bottom shows the icon representing RPA bound to DNA in part (a). [Part (a) adapted from S. J. Flint et al., 2000, *Virology: Molecular Biology, Pathogenesis, and Control*, ASM Press. Part (b) adapted from J. M. Gulbis et al., 1996, *Cell* 87:297. Part (c) adapted from A. Bochkarev et al., 1997, *Nature* 385:176.]

Several other eukaryotic proteins that function in DNA replication are not depicted in Figure 4-31. For example, topoisomerase I associates with the parental DNA ahead of the replicative helicase, i.e., to the left of T-antigen in Figure 4-31, to remove torsional stress introduced by the unwinding

of the parental strands (see Figure 4-8a). Ribonuclease H and FEN I remove the ribonucleotides at the 5' ends of Okazaki fragments; these are replaced by deoxynucleotides added by DNA polymerase δ as it extends the upstream Okazaki fragment. Successive Okazaki fragments are coupled by DNA

EXPERIMENTAL FIGURE 4-32 Bidirectional replication in SV40 DNA. Electron microscopy of replicating SV40 DNA indicates bidirectional growth of DNA strands from an origin. The replicating viral DNA from SV40-infected cells was cut by the restriction enzyme *EcoRI*, which recognizes one site in the circular DNA. This was done to provide a landmark for a specific sequence in the SV40 genome: the *EcoRI* recognition sequence is now easily recognized as the ends of linear DNA molecules visualized by electron microscopy. Electron micrographs of *EcoRI*-cut replicating SV40 DNA molecules showed a collection of cut molecules with increasingly longer replication “bubbles,” whose centers are a constant distance from each end of the cut molecules. This finding is consistent with chain growth in two directions from a common origin located at the center of a bubble, as illustrated in the corresponding diagrams. [See G. C. Fareed et al., 1972, *J. Virol.* **10**:484; photographs courtesy of N. P. Salzman.]

ligase through standard 5'→3' phosphoester bonds. Other specialized DNA polymerases are involved in repair of mismatches and damaged lesions in DNA (see Section 4.7).

DNA Replication Occurs Bidirectionally from Each Origin

As indicated in Figures 4-30 and 4-31, both parental DNA strands that are exposed by local unwinding at a replication fork are copied into a daughter strand. In theory, DNA replication from a single origin could involve one replication fork that moves in one direction. Alternatively, two replication forks might assemble at a single origin and then move in opposite directions, leading to *bidirectional growth* of both daughter strands. Several types of experiments, including the one shown in Figure 4-32, provided early evidence in support of bidirectional strand growth.

The general consensus is that all prokaryotic and eukaryotic cells employ a bidirectional mechanism of DNA replication. In the case of SV40 DNA, replication is initiated by binding of two large T-antigen hexameric helicases to the single SV40 origin and assembly of other proteins to form two replication forks. These then move away from the SV40 origin in opposite directions, with leading- and lagging-strand synthesis occurring at both forks. As shown in Figure 4-33, the left replication fork extends DNA synthesis in the leftward direction; similarly, the right replication fork extends DNA synthesis in the rightward direction.

Unlike SV40 DNA, eukaryotic chromosomal DNA molecules contain multiple replication origins separated by tens to hundreds of kilobases. A six-subunit protein called ORC, for origin recognition complex, binds to each origin and associates with other proteins required to load cellular hexameric helicases composed of six homologous MCM proteins. Two opposed MCM helicases separate the parental strands at an origin, with RPA proteins binding to the

resulting single-stranded DNA. Synthesis of primers and subsequent steps in replication of cellular DNA are thought to be analogous to those in SV40 DNA replication (see Figures 4-31 and 4-33).

Replication of cellular DNA and other events leading to proliferation of cells are tightly regulated, so that the appropriate numbers of cells constituting each tissue are produced during development and throughout the life of an organism. Control of the initiation step is the primary mechanism for regulating cellular DNA replication. Activation of MCM helicase activity, which is required to initiate cellular DNA replication, is regulated by specific protein kinases called S-phase **cyclin-dependent kinases**. Other cyclin-dependent kinases regulate additional aspects of cell proliferation, including the complex process of mitosis by which a eukaryotic cell divides into two daughter cells. Mitosis and another specialized type of cell division called meiosis, which generates haploid sperm and egg cells, are discussed in Chapter 5. We discuss the various regulatory mechanisms that determine the rate of cell division in Chapter 20.

FIGURE 4-33 Bidirectional mechanism of DNA replication.

The left replication fork here is comparable to the replication fork diagrammed in Figure 4-31, which also shows proteins other than large T-antigen. **Top:** Two large T-antigen hexameric helicases first bind at the replication origin in opposite orientations. **Step 1:** Using energy provided from ATP hydrolysis, the helicases move in opposite directions, unwinding the parental DNA and generating single-strand templates that are bound by RPA proteins. **Step 2:** Primase–Pol α complexes synthesize short primers (red) base-paired to each of the separated parental strands. **Step 3:** PCNA–Rfc–Pol δ/ϵ complexes replace the primase–Pol α complexes and extend the short primers, generating the leading strands (dark green) at each replication fork. **Step 4:** The helicases further unwind the parental strands, and RPA proteins bind to the newly exposed single-strand regions. **Step 5:** PCNA–Rfc–Pol δ complexes extend the leading strands further. **Step 6:** Primase–Pol α complexes synthesize primers for lagging-strand synthesis at each replication fork. **Step 7:** PCNA–Rfc–Pol δ complexes displace the primase–Pol α complexes and extend the lagging-strand Okazaki fragments (light green), which eventually are ligated to the 5' ends of the leading strands. The position where ligation occurs is represented by a circle. Replication continues by further unwinding of the parental strands and synthesis of leading and lagging strands as in Steps 4–7. Although depicted as individual steps for clarity, unwinding and synthesis of leading and lagging strands occur concurrently.

KEY CONCEPTS of Section 4.5

DNA Replication

- Each strand in a parental duplex DNA acts as a template for synthesis of a daughter strand and remains base-paired to the new strand, forming a daughter duplex (semiconservative mechanism). New strands are formed in the 5'→3' direction.
- Replication begins at a sequence called an *origin*. Each eukaryotic chromosomal DNA molecule contains multiple replication origins.
- DNA polymerases, unlike RNA polymerases, cannot unwind the strands of duplex DNA and cannot initiate synthesis of new strands complementary to the template strands.
- At a replication fork, one daughter strand (the leading strand) is elongated continuously. The other daughter strand (the lagging strand) is formed as a series of discontinuous Okazaki fragments from primers synthesized every few hundred nucleotides (Figure 4-30).
- The ribonucleotides at the 5' end of each Okazaki fragment are removed and replaced by elongation of the 3' end of the next Okazaki fragment. Finally, adjacent Okazaki fragments are joined by DNA ligase.
- Helicases use energy from ATP hydrolysis to separate the parental (template) DNA strands which are initially bound

by multiple copies of a single-stranded DNA-binding protein, RPA. Primase synthesizes a short RNA primer, which remains base-paired to the template DNA. This initially is extended at the 3' end by DNA polymerase α (Pol α), resulting in a short (5')RNA-(3')DNA daughter strand.

- Most of the DNA in eukaryotic cells is synthesized by Pol δ and Pol ϵ , which take over from Pol α and continue elongation of the daughter strand in the 5'→3' direction. Pol δ synthesizes most of the length of the lagging strand, while Pol ϵ synthesizes the leading strand. Pol δ and Pol ϵ remain stably associated with the template by binding to Rfc protein, which in turn binds to PCNA, a trimeric protein that encircles the daughter duplex DNA, functioning as a sliding clamp (see Figure 4-31).

- DNA replication generally occurs by a bidirectional mechanism in which two replication forks form at an origin and move in opposite directions, with both template strands being copied at each fork (see Figure 4-33).

- Synthesis of eukaryotic DNA *in vivo* is regulated by controlling the activity of the MCM helicases that initiate DNA replication at multiple origins spaced along chromosomal DNA.

4.6 DNA Repair and Recombination

Damage to DNA is unavoidable and arises in many ways. DNA damage can be caused by spontaneous cleavage of chemical bonds in DNA, by environmental agents such as ultraviolet and ionizing radiation, and by reaction with genotoxic chemicals that are by-products of normal cellular metabolism or occur in the environment. A change in the normal DNA sequence, called a **mutation**, can occur during replication when a DNA polymerase inserts the wrong nucleotide as it reads a damaged template. Mutations also occur at a low frequency as the result of copying errors introduced by DNA polymerases when they replicate an undamaged template. If such mutations were left uncorrected, cells might accumulate so many mutations that they could no longer function properly. In addition, the DNA in germ cells might incur too many mutations for viable offspring to be formed. Thus the prevention of DNA sequence errors in all types of cells is important for survival, and several cellular mechanisms for repairing damaged DNA and correcting sequence errors have evolved. One of these mechanisms for repairing double-stranded DNA breaks, by the process of recombination, is also used by eukaryotic cells to generate new combinations of maternal and paternal genes on each chromosome through the exchange of segments of the chromosomes during the production of germ cells (e.g., sperm and eggs).

Significantly, defects in DNA repair mechanisms and cancer are closely related. When repair mechanisms are compromised, mutations accumulate in the cell's DNA. If these mutations affect genes that are normally involved in the careful regulation of cell division, cells can begin to divide uncontrollably, leading to tumor formation, and cancer. Chapter 25 outlines in detail how cancer arises from defects in DNA repair. We will encounter a few examples in this section as well, as we first consider the ways in which DNA

integrity can be compromised, and then discuss the repair mechanisms that cells have evolved to ensure the fidelity of this very important molecule.

DNA Polymerases Introduce Copying Errors and Also Correct Them

The first line of defense in preventing mutations is DNA polymerase itself. Occasionally, when replicative DNA polymerases progress along the template DNA, an incorrect nucleotide is added to the growing 3' end of the daughter strand. *E. coli* DNA polymerases, for instance, introduce about 1 incorrect nucleotide per 10^4 (ten thousand) polymerized nucleotides. Yet the measured mutation rate in bacterial cells is much lower: about 1 mistake in 10^9 (one billion) nucleotides incorporated into a growing strand. This remarkable accuracy is largely due to *proofreading* by *E. coli* DNA polymerases. Eukaryotic Pol δ and Pol ϵ employ a similar mechanism.

Proofreading depends on a 3'→5' *exonuclease activity* of some DNA polymerases. When an incorrect base is incorporated during DNA synthesis, base pairing between the 3' nucleotide of the nascent strand and the template strand does not occur. As a result, the polymerase pauses, then transfers the 3' end of the growing chain to the exonuclease site, where the incorrect mispaired base is removed (Figure 4-34). Then the 3' end is transferred back to the polymerase site, where this region is copied correctly. All three *E. coli* DNA polymerases have proofreading activity, as do the two eukaryotic DNA polymerases, δ and ϵ , used for replication of most chromosomal DNA in animal cells. It seems likely that proofreading is indispensable for all cells to avoid excessive mutations.

Chemical and Radiation Damage to DNA Can Lead to Mutations

DNA is continually subjected to a barrage of damaging chemical reactions; estimates of the number of DNA damage events in a single human cell range from 10^4 to 10^6 per day! Even if DNA were not exposed to damaging chemicals, certain aspects of DNA structure are inherently unstable. For example, the bond connecting a purine base to deoxyribose is prone to hydrolysis at a low rate under physiological conditions, leaving a sugar without an attached base. Thus coding information is lost, and this can lead to a mutation during DNA replication. Normal cellular reactions, including the movement of electrons along the electron-transport chain in mitochondria and lipid oxidation in peroxisomes, produce several chemicals that react with and damage DNA, including hydroxyl radicals and superoxide (O_2^-). These too can cause mutations, including those that lead to cancers.

Many spontaneous mutations are **point mutations**, which involve a change in a single base pair in the DNA sequence. This can introduce a stop codon, causing a *nonsense* mutation as discussed earlier, or a change in the amino acid sequence of an encoded protein, called a *missense* mutation. *Silent* mutations do not change the amino acid sequence (e.g., GAG to GAA; both encode glutamine). Point mutations can

FIGURE 4-34 Proofreading by DNA polymerase. All DNA polymerases have a similar three-dimensional structure, which resembles a half-opened right hand. The “fingers” bind the single-stranded segment of the template strand, and the polymerase catalytic activity (Pol) lies in the junction between the fingers and palm. As long as the correct nucleotides are added to the 3′ end of the growing strand, it remains in the polymerase site. Incorporation of an incorrect

base at the 3′ end causes melting of the newly formed end of the duplex. As a result, the polymerase pauses, and the 3′ end of the growing strand is transferred to the 3′→5′ exonuclease site (Exo) about 3 nm away, where the mispaired base and probably other bases are removed. Subsequently, the 3′ end flips back into the polymerase site and elongation resumes. [Adapted from C. M. Joyce and T. T. Steitz, 1995, *J. Bacteriol.* **177**:6321, and S. Bell and T. Baker, 1998, *Cell* **92**:295.]

also occur in a non-protein-coding DNA sequence that functions in the regulation of a gene’s transcription, as discussed in Chapter 7. One of the most frequent point mutations comes from *deamination* of a cytosine (C) base, which converts it into a uracil (U) base. In addition, the common modified base 5-methyl cytosine forms thymine when it is deaminated. If these alterations are not corrected before the DNA is replicated, the cell will use the strand containing U or

T as template to form a U·A or T·A base pair, thus creating a permanent change to the DNA sequence (Figure 4-35).

High-Fidelity DNA Excision Repair Systems Recognize and Repair Damage

In addition to proofreading, cells have other repair systems for preventing mutations due to copying errors and exposure

FIGURE 4-35 Deamination leads to point mutations. A spontaneous point mutation can form by deamination of 5-methylcytosine (C) to form thymine (T). If the resulting T·G base pair is not restored to the normal C·G base pair by base excision-repair mechanisms (step **1**), it

will lead to a permanent change in sequence (i.e., a mutation) following DNA replication (step **2**). After one round of replication, one daughter DNA molecule will have the mutant T·A base pair and the other will have the wild-type C·G base pair.

to chemicals and radiation. Several DNA excision-repair systems that normally operate with a high degree of accuracy have been well studied. These systems were first elucidated through a combination of genetic and biochemical studies in *E. coli*. Homologs of the key bacterial proteins exist in eukaryotes from yeast to humans, indicating that these error-free mechanisms arose early in evolution to protect DNA integrity. Each of these systems functions in a similar manner—a segment of the damaged DNA strand is excised, and the gap is filled by DNA polymerase and ligase using the complementary DNA strand as template.

We will now turn to a closer look at some of the mechanisms of DNA repair, ranging from repair of single base mutations to repair of DNA broken across both strands. Some of these accomplish their repairs with great accuracy; others are less precise.

Base Excision Repairs T-G Mismatches and Damaged Bases

In humans, the most common type of point mutation is a C to T, which is caused by deamination of 5-methyl C to T (see Figure 4-35). The conceptual problem with *base excision repair* in this case is determining which is the normal and which is the mutant DNA strand, and repairing the latter so that it is properly base-paired with the normal strand. But since a G·T mismatch is almost invariably caused by chemical conversion of C to U or 5-methyl C to T, the repair system evolved to remove the T and replace it with a C.

The G·T mismatch is recognized by a DNA glycosylase that flips the thymine base out of the helix and then hydrolyzes the bond that connects it to the sugar-phosphate DNA backbone. Following this initial incision, an apurinic (AP) endonuclease cuts the DNA strand near the abasic site. The deoxyribose phosphate lacking the base is then removed and replaced with a C by a specialized repair DNA polymerase that reads the G in the template strand (Figure 4-36).

As mentioned earlier, this repair must take place prior to DNA replication, because the incorrect base in this pair, T, occurs naturally in normal DNA. Consequently, it would be able to engage in normal Watson-Crick base pairing during replication, generating a stable point mutation that is now unable to be recognized by repair mechanisms (see Figure 4-35, step 2).

Human cells contain a battery of glycosylases, each of which is specific for a different set of chemically modified DNA bases. For example, one removes 8-oxyguanine, an oxidized form of guanine, allowing its replacement by an undamaged G, and others remove bases modified by alkylating agents. The resulting nucleotide lacking a base is then replaced by the repair mechanism discussed above. A similar mechanism also functions in the repair of lesions resulting from *depurination*, the loss of a guanine or adenine base from DNA resulting from hydrolysis of the glycosylic bond between deoxyribose and the base. Depurination occurs spontaneously and is fairly common in mammals. The resulting abasic sites, if left unrepaired, generate mutations during DNA replication because they cannot specify the appropriate paired base.

FIGURE 4-36 Base excision repair of a T·G mismatch. A DNA glycosylase specific for G·T mismatches, usually formed by deamination of 5-mC residues (see Figure 4-35), flips the thymine base out of the helix and then cuts it away from the sugar-phosphate DNA backbone (step 1), leaving just the deoxyribose (black dot). An endonuclease specific for the resultant baseless site (apurinic endonuclease I, APE1) then cuts the DNA backbone (step 2), and the deoxyribose phosphate is removed by an endonuclease, apurinic lyase (AP lyase), associated with DNA polymerase β , a specialized DNA polymerase used in repair (step 3). The gap is then filled in by DNA Pol β and sealed by DNA ligase (step 4), restoring the original G·C base pair. [Adapted from O. Schärer, 2003, *Angewandte Chemie* 42:2946.]

Mismatch Excision Repairs Other Mismatches and Small Insertions and Deletions

Another process, also conserved from bacteria to humans, principally eliminates base-pair mismatches and insertions or deletions of one or a few nucleotides that are accidentally introduced by DNA polymerases during replication. As with base excision repair of a T in a T·G mismatch, the conceptual problem with *mismatch excision repair* is determining which is the normal and which is the mutant DNA strand, and repairing the latter. How this happens in human cells is not known with certainty. It is thought that the proteins that bind to the mismatched segment of DNA distinguish the template and daughter strands; then the mispaired segment of the daughter strand—the one with the replication error—is excised and repaired to become an exact complement of the template strand (Figure 4-37). In contrast to base excision repair, mismatch excision repair occurs after DNA replication.

 Predisposition to a colon cancer known as hereditary nonpolyposis colorectal cancer results from an inherited loss-of-function mutation in one copy of either the *MLH1* or the

FIGURE 4-37 Mismatch excision repair in human cells. The mismatch excision-repair pathway corrects errors introduced during replication. A complex of the MSH2 and MSH6 proteins (bacterial MutS homologs 1 and 6) binds to a mispaired segment of DNA in such a way as to distinguish between the template and newly synthesized daughter strands (step **1**). This triggers binding of MLH1 and PMS2 (both homologs of bacterial MutL). The resulting DNA-protein complex then binds an endonuclease that cuts the newly synthesized daughter strand. Next a DNA helicase unwinds the helix, and an exonuclease removes several nucleotides from the cut end of the daughter strand, including the mismatched base (step **2**). Finally, as with base excision repair, the gap is then filled in by a DNA polymerase (Pol δ , in this case) and sealed by DNA ligase (step **3**).

MSH2 gene. The MSH2 and MLH1 proteins are essential for DNA mismatch repair (see Figure 4-37). Cells with at least one functional copy of each of these genes exhibit normal mismatch repair. However, tumor cells frequently arise from those cells that have experienced a random mutation in the second copy; when both copies of one gene are not functional, the mismatch repair system is lost. Inactivating mutations in these genes are also common in noninherited forms of colon cancer. ■

Nucleotide Excision Repairs Chemical Adducts that Distort Normal DNA Shape

Cells use *nucleotide excision repair* to fix DNA regions containing chemically modified bases, often called chemical adducts, that distort the normal shape of DNA locally. A key to this type of repair is the ability of certain proteins to slide along the surface of a double-stranded DNA molecule looking

FIGURE 4-38 Formation of thymine-thymine dimers. The most common type of DNA damage caused by UV irradiation, thymine-thymine dimers, can be repaired by an excision-repair mechanism.

for bulges or other irregularities in the shape of the double helix. For example, this mechanism repairs *thymine-thymine dimers*, a common type of damage caused by UV light (Figure 4-38); these dimers interfere with both replication and transcription of DNA.

Figure 4-39 illustrates how the nucleotide excision-repair system repairs damaged DNA. Some 30 proteins are involved in this repair process, the first of which were identified through a study of the defects in DNA repair in cultured cells from individuals with xeroderma pigmentosum, a hereditary disease associated with a predisposition to cancer. Individuals with this disease frequently develop the skin cancers called melanomas and squamous cell carcinomas if their skin is exposed to the UV rays in sunlight. Cells of affected patients lack a functional nucleotide excision-repair system. Mutations in any of at least seven different genes, called XP-A through XP-G, lead to inactivation of this repair system and cause xeroderma pigmentosum; all produce the same phenotype and have the same consequences. The roles of most of these XP proteins in nucleotide excision repair are now well understood (see Figure 4-39). ■

Remarkably, five polypeptide subunits of TFIIH, a general transcription factor required for transcription of all genes

FIGURE 4-39 Nucleotide excision repair in human cells. A DNA lesion that causes distortion of the double helix, such as a thymine dimer, is initially recognized by a complex of the XP-C (xeroderma pigmentosum C protein) and 23B proteins (step **1**). This complex then recruits transcription factor TFIIH, whose helicase subunits, powered by ATP hydrolysis, partially unwind the double helix. XP-G and RPA proteins then bind to the complex and further unwind and stabilize the helix until a bubble of ≈ 25 bases is formed (step **2**). Then XP-G (now acting as an endonuclease) and XP-F, a second endonuclease, cut the damaged strand at points 24–32 bases apart on each side of the lesion (step **3**). This releases the DNA fragment with the damaged bases, which is degraded to mononucleotides. Finally the gap is filled by DNA polymerase exactly as in DNA replication, and the remaining nick is sealed by DNA ligase (step **4**). [Adapted from J. Hoeijmakers, 2001, *Nature* 411:366, and O. Schärer, 2003, *Angewandte Chemie* 42:2946.]

(see Figure 7-16) are also required for nucleotide excision repair in eukaryotic cells. Two of these subunits have homology to helicases, as shown in Figure 4-39. In transcription, the helicase activity of TFIIH unwinds the DNA helix at the start site, allowing RNA polymerase to initiate (see Figure 7-16). It appears that nature has used a similar protein assembly in two different cellular processes that require helicase activity.

The use of shared subunits in transcription and DNA repair may help explain the observation that DNA damage in higher eukaryotes is repaired at a much faster rate in regions of the genome being actively transcribed than in nontranscribed regions—so-called transcription-coupled repair. Since only a small fraction of the genome is transcribed in any one cell in higher eukaryotes, transcription-coupled repair efficiently directs repair efforts to the most critical regions. In this system, if an RNA polymerase becomes stalled at a lesion on DNA (e.g., a thymine-thymine dimer), a small protein, CSB, is recruited to the RNA polymerase; this triggers opening of the DNA helix at that point, recruitment of TFIIH, and the reactions of steps **2** through **4** depicted in Figure 4-39.

Two Systems Utilize Recombination to Repair Double-Strand Breaks in DNA

Ionizing radiation (e.g., x- and γ -radiation) and some anticancer drugs cause double-strand breaks in DNA. These are particularly severe lesions because incorrect rejoining of double strands of DNA can lead to gross chromosomal rearrangements that can affect the functioning of genes. For example, incorrect joining could create a “hybrid” gene that codes for the N-terminal portion of one amino acid sequence fused to the C-terminal portion of a completely different amino acid sequence; or a chromosomal rearrangement could bring the promoter of one gene into close proximity to the coding region of another gene, changing the level or cell type in which that gene is expressed.

Two systems have evolved to repair double-strand breaks: *homologous recombination*, discussed in the next section, and *nonhomologous end-joining (NHEJ)*, which is error-prone, since several nucleotides are invariably lost at the point of repair.

Error-Prone Repair by Nonhomologous End-Joining The predominant mechanism for repairing double-strand breaks in multicellular organisms involves rejoining the nonhomologous ends of two DNA molecules. Even if the joined DNA fragments come from the same chromosome, the repair process results in loss of several base pairs at the joining point (Figure 4-40). Formation of such a possibly mutagenic deletion is one example of how repair of DNA damage can introduce mutations.

Since movement of DNA within the protein-dense nucleus is fairly minimal, the correct ends are generally rejoined together, albeit with loss of base pairs. Occasionally, however, broken ends from different chromosomes are joined together,

FIGURE 4-40 Nonhomologous end-joining. When sister chromatids are not available to help repair double-strand breaks, nucleotide sequences are butted together that were not apposed in the unbroken DNA. These DNA ends are usually from the same chromosome locus, and when linked together, several base pairs are lost. Occasionally, ends from different chromosomes are accidentally joined together. A complex of two proteins, Ku and DNA-dependent protein kinase (DNA-PK), binds to the ends of a double-strand break (step 1). After formation of a synapse, the ends are further processed by nucleases, resulting in removal of a few bases (step 2), and the two double-stranded molecules are ligated together (step 3). As a result, the double-strand break is repaired, but several base pairs at the site of the break are removed. [Adapted from G. Chu, 1997, *J. Biol. Chem.* **272**:24097; M. Lieber et al., 1997, *Curr. Opin. Genet. Devel.* **7**:99; and D. van Gant et al., 2001, *Nature Rev. Genet.* **2**:196.]

leading to translocation of pieces of DNA from one chromosome to another. Such translocations may generate chimeric genes that can have drastic effects on normal cell function, such as uncontrollable cell growth, which is the hallmark of cancer (see Figure 6-42). The devastating effects of double-strand breaks make these the “most unkindest cuts of all,” to borrow a phrase from Shakespeare’s *Julius Caesar*.

Homologous Recombination Can Repair DNA Damage and Generate Genetic Diversity

At one time homologous recombination was thought to be a minor repair process in human cells. This changed when it was realized that several human cancers are potentiated by inherited mutations in genes essential for homologous recombination repair (see Table 25-1). For example, some women with an inherited susceptibility to breast cancer have

a mutation in one allele of either the *BRCA-1* or the *BRCA-2* genes that encode proteins participating in this repair process. Loss or inactivation of the second allele inhibits the homologous recombination repair pathway and thus tends to induce cancer in mammary or ovarian epithelial cells. Yeasts can repair double-strand breaks induced by γ -irradiation. Isolation and analysis of radiation-sensitive (*RAD*) mutants that are deficient in this repair system facilitated study of the process. Virtually all the yeast *Rad* proteins have homologs in the human genome, and the human and yeast proteins function in an essentially identical fashion.

A variety of DNA lesions that are not repaired by mechanisms discussed earlier can be repaired by mechanisms in which the damaged sequence is copied from an undamaged copy of the same or highly homologous DNA sequence on the homologous chromosome of diploid organisms or the sister chromosome following DNA replication in haploid and diploid organisms. These mechanisms involve an exchange of strands between separate DNA molecules and hence are referred to as **DNA recombination**.

In addition to providing a mechanism for DNA repair, similar recombination mechanisms generate genetic diversity among the individuals of a species by causing the exchange of large regions of chromosomes between the maternal and paternal pair of homologous chromosomes during *meiosis*, the special type of cellular division that generates germ cells (sperm and eggs) (Figure 5-3). In fact, the exchange of regions of homologous chromosomes, called *crossing-over*, is required for proper segregation of chromosomes during the first meiotic cell division. Meiosis and the consequences of generating new combinations of maternal and paternal genes on one chromosome by recombination are discussed further in Chapter 5. The mechanisms leading to proper segregation of chromosomes during meiosis are discussed in Chapter 20. Here we will focus on the molecular mechanisms of DNA recombination, highlighting the exchange of DNA strands between two recombining DNA molecules.

Repair of a Collapsed Replication Fork An example of recombinational DNA repair is the repair of a “collapsed” replication fork. If a break in the phosphodiester backbone of one DNA strand is not repaired before a replication fork passes, the replicated portions of the daughter chromosomes become separated when the replication helicase reaches the break in the parental DNA strand because there are no covalent bonds between the two fragments of the parental strand on either side of the nick. This process is called *replication fork collapse* (Figure 4-41, step 1). If it is not repaired, it is generally lethal to at least one daughter cell following cell division, because of the loss of genetic information between the break and the end of the chromosome. The recombination process that repairs the resulting double-stranded break and regenerates a replication fork involves multiple enzymes and other proteins, only some of which are mentioned here.

The first step in the repair of the double-strand break is exonucleolytic digestion of the strand with its 5' end at the

FIGURE 4-41 Recombinational repair of a collapsed replication fork. Parental strands are light and dark blue. The leading daughter strand is dark red, and the lagging daughter strand pink. Diagonal lines in step 3 and beyond represent a single phosphodiester bond from the DNA strand of the corresponding color. Small black arrows following step 4 represent cleavage of the phosphodiester bonds at the crossover of DNA strands in the Holliday structure. See <http://www.sheffield.ac.uk/mbb/ruva> for an animation of branch migration catalyzed by *E. coli* proteins RuvA and RuvB. See the text for a discussion. [Adapted from D. L. Nelson and M. M. Cox, 2005, *Lehninger Principles of Biochemistry*, 4th ed., W. H. Freeman and Company.]

broken end of DNA, leaving the strand with a 3' end at the break single-stranded (Figure 4-41, step 2). The lagging nascent strand (pink) base paired to the unbroken parent strand (dark blue) is ligated to the unreplicated portion of the

parent chromosome (light blue), as shown in Figure 4-41, step 2. A critical protein required for the next step is RecA in bacteria, or the homologous Rad51 in *S. cerevisiae* and other eukaryotes. Multiple RecA/Rad51 molecules bind to the single-stranded DNA and catalyze its hybridization to a perfectly or nearly perfectly complementary sequence in another, homologous, double-stranded DNA molecule. The complementary strand of this target double-stranded DNA (dark blue) is displaced as a single-stranded loop of DNA over the region of hybridization to the invading strand (Figure 4-41, step 3). This RecA/Rad51 catalyzed invasion of a duplex DNA by a single-stranded complement of one of the strands is key to the recombination process. Since no base pairs are lost or gained in this process, called **strand invasion**, it does not require an input of energy.

Next, the hybrid region between target DNA and the invading strand is extended in the direction away from the break by proteins that use energy from ATP hydrolysis. This process is called **branch migration** (Figure 4-41, step 4) because the position where the target DNA strand crosses from one complementary strand (dark blue) to its complement in the broken DNA molecule (dark red), i.e. the pink diagonal line after step 3, is called a **branch** in the DNA structure. In this diagram, the diagonal lines represent only one phosphodiester bond. Molecular modeling and other studies show that the first base on either side of the branch is base-paired to a complementary nucleotide. As this branch *migrates* to the left, the number of base pairs remains constant; one new base pair formed with the (red) invading strand is matched by the loss of one base pair with the parental (blue) strand.

When the region of hybrid extends beyond the 5' end of the broken strand (light blue), the single-stranded parental DNA strand generated (light blue) base pairs with the complementary region of the other parental strand (dark blue) that becomes single-stranded as the branch migrates to the left (Figure 4-41, step 4). The resulting structure is called a **Holliday structure**, after Robin Holliday, the geneticist who first proposed it as an intermediate in genetic recombination. Again, the diagonal lines in the diagram following step 4 represent single phosphodiester bonds, and all bases in the Holliday structure are base-paired to complementary bases in the parental strands. Cleavage of the phosphodiester bonds that *cross over* from one parental strand to the other (step 5) and ligation of the 5' and 3' ends base paired to the same parental strands (step 6) result in the generation of a structure similar to a replication fork. Rebinding of replication fork proteins results in extension of the leading strand past the point of the original strand break and re-initiation of lagging-strand synthesis (step 7), thus regenerating a replication fork. The overall process allows the ligated upper strand in the lower molecule following step 3 to serve as template for extension of the leading strand in step 7.

Double-Stranded DNA Break Repair by Homologous Recombination A similar mechanism called **homologous recombination** can repair a double-strand break in a chromosome and can also exchange large segments of two double-stranded

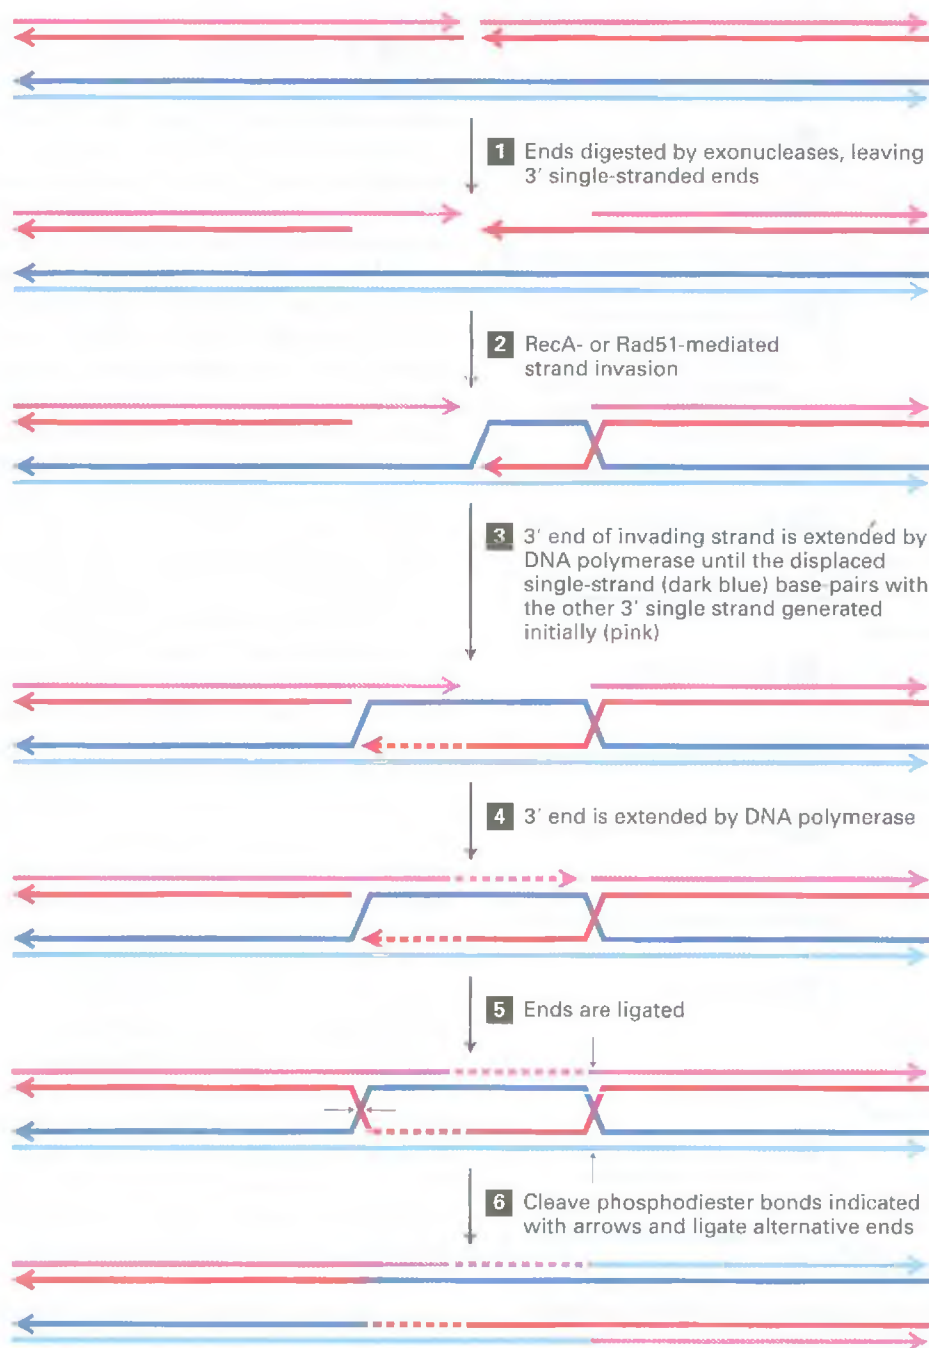

FIGURE 4-42 Double-strand DNA break repair by homologous recombination. For simplicity, each DNA double helix is represented by two parallel lines with the polarities of the strands indicated by arrowheads at their 3' ends. The upper molecule has a double-strand break.

Note that in the diagram of the upper DNA molecule the strand with its 3' end at the right is on the top, while in the diagram of the lower DNA molecule this strand is drawn on the bottom. See the text for discussion. [Adapted from T. L. Orr-Weaver and J. W. Szostak, 1985, *Microbiol. Rev.* **49**:33.]

DNA molecules (Figure 4-42). First, the broken ends of the DNA molecule are resected by exonucleases that leave a single-stranded region of DNA with a 3' end (step **1**). RecA in bacteria and Rad51 in eukaryotes then catalyzes strand invasion of one of these 3' ends into the homologous region of the homologous chromosome as discussed above for repair of a collapsed replication fork (step **2**). The 3' end of the invading DNA strand is then extended by a DNA polymerase,

displacing the parental strand as an enlarging single-stranded loop of DNA (dark blue) (step **3**). When the loop extends to a sequence that is complementary to the other broken end of DNA (the fragment on the left following step **1**), the complementary sequences base-pair (diagram following step **3**). This 3' end is then extended by a DNA polymerase using the displaced single-stranded loop of parental DNA (dark blue) as template (step **4**).

FIGURE 4-43 Alternative resolution of a Holliday structure. Diagonal and vertical lines represent a single phosphodiester bond. It is simplest to diagram the process by rotating the diagram of the bottom molecule 180° so that the top and bottom molecules have the same strand orientations. Cutting the bonds as shown in **1** and

ligating the ends as indicated regenerates the original chromosomes. Cutting the strands as shown in **2** and religating as shown at the bottom generates recombinant chromosomes. See <http://engels.genetics.wisc.edu/Holliday/holliday3D.html> for a three-dimensional animation of the Holliday structure and its resolution.

Next, the new 3' ends are ligated (step **5**) to the exonuclease-digested 5' ends. This generates two Holliday structures in the paired molecules (step **5**). Branch migration of these Holliday structures can occur in either direction (not diagrammed). Finally, cleavage of the strands at the positions shown by the arrows, and ligation of the alternative 5' and 3' ends at each cleaved Holliday structure generates two *recombinant* chromosomes that contain the DNA of one *parental* DNA molecule on one side of the break point (pink and red strands), and the DNA of the other parental DNA molecule on the other side of the initial break point (light and dark blue) (step **6**). The region in the immediate vicinity of the initial break point forms a *heteroduplex*, in which one strand from one parent is base-paired to the complementary strand of the other parent (pink or red strand base-paired to the light or dark blue strand). Base-pair mismatches between the two parental strands are usually repaired by repair mechanisms discussed above to generate a complementary base pair. In the process, sequence differences between the two parents are lost, a process referred to as *gene conversion*.

Figure 4-43 diagrams how cleavage of one or the other pair of strands at the four-way strand junction in the Holliday structure generates parental or recombinant molecules. This process, called *resolution* of the Holliday structure, separates DNA molecules initially joined by RecA/Rad51-catalyzed strand invasion. Each Holliday structure in the intermediate following Figure 4-42, step **5**, can be cleaved and religated in the two possible ways shown by the two sets of small black arrows in Figure 4-43. Consequently, there are four possible products of the recombination process shown in Figure 4-42. Two of these regenerate the parental chromosomes [with the exception of the heteroduplex region at the break point that is repaired into the sequence of one parent or the other (gene conversion)]. The other two possible products generate recombinant chromosomes as shown in Figure 4-42.

KEY CONCEPTS of Section 4.6

DNA Repair and Recombination

- Changes in the DNA sequence result from copying errors and the effects of various physical and chemical agents.
- Many copying errors that occur during DNA replication are corrected by the proofreading function of DNA polymerases that can recognize incorrect (mismatched) bases at the 3' end of the growing strand and then remove them by an inherent 3'→5' exonuclease activity (see Figure 4-34).
- Eukaryotic cells have three excision-repair systems for correcting mismatched bases and for removing UV-induced thymine-thymine dimers or large chemical adducts from DNA. Base excision repair, mismatch repair, and nucleotide excision repair operate with high accuracy and generally do not introduce errors.
- Repair of double-strand breaks by the nonhomologous end-joining pathway can link segments of DNA from different chromosomes, possibly forming an oncogenic translocation. The repair mechanism also produces a small deletion, even when segments from the same chromosome are joined.
- Error-free repair of double-strand breaks in DNA is accomplished by homologous recombination using the undamaged sister chromatid as template.
- Inherited defects in the nucleotide excision-repair pathway, as in individuals with xeroderma pigmentosum, predispose them to skin cancer. Inherited colon cancer frequently is associated with mutant forms of proteins essential for the mismatch repair pathway. Defects in repair by homologous recombination are associated with inheritance of one mutant allele of the *BRCA-1* or *BRCA-2* gene and result in predisposition to breast and uterine cancer.

4.7 Viruses: Parasites of the Cellular Genetic System

Viruses are obligate, intracellular parasites. They cannot reproduce by themselves and must commandeer a host cell's machinery to synthesize viral proteins and in some cases to replicate the viral genome. RNA viruses, which usually replicate in the host-cell cytoplasm, have an RNA genome, and DNA viruses, which commonly replicate in the host-cell nucleus, have a DNA genome (see Figure 4-1). Viral genomes may be single- or double-stranded, depending on the specific type of virus. The entire infectious virus particle, called a **virion**, consists of the nucleic acid and an outer shell of protein that both protects the viral nucleic acid and functions in the process of host-cell infection. The simplest viruses contain only enough RNA or DNA to encode four proteins; the most complex can encode ≈ 200 proteins. In addition to their obvious importance as causes of disease, viruses are extremely useful as research tools in the study of basic biological processes, such as those discussed in this chapter.

Most Viral Host Ranges Are Narrow

The surface of a virion contains many copies of one type of protein that binds specifically to multiple copies of a receptor protein on a host cell. This interaction determines the **host range**—the group of cell types that a virus can infect—and begins the infection process. Most viruses have a rather limited host range.

A virus that infects only bacteria is called a **bacteriophage**, or simply a *phage*. Viruses that infect animal or plant cells are referred to generally as animal viruses or plant viruses. A few viruses can grow in both plants or animals and the insects that feed on them. The highly mobile insects serve as vectors for transferring such viruses between susceptible animal or plant hosts. Wide host ranges are also characteristic of some strictly animal viruses, such as vesicular stomatitis virus, which grows in insect vectors and in many different types of mammals. Most animal viruses, however, do not cross phyla, and some (e.g., poliovirus) infect only closely related species such as primates. The host-cell range of some animal viruses is further restricted to a limited number of cell types because only these cells have appropriate surface receptors to which the virions can attach. One example is poliovirus, which only infects cells in the intestine and, unfortunately, motor neurons in the spinal chord, causing paralysis. Another is HIV-1, discussed further below, which infects cells essential for the immune response called $CD4^+$ T-lymphocytes, causing AIDS (see Chapter 23), and certain neurons and other cells of the central nervous system called glial cells.

Viral Capsids Are Regular Arrays of One or a Few Types of Protein

The nucleic acid of a virion is enclosed within a protein coat, or **capsid**, composed of multiple copies of one protein or a few different proteins, each of which is encoded by a single

viral gene. Because of this structure, a virus is able to encode all the information for making a relatively large capsid in a small number of genes. This efficient use of genetic information is important, since only a limited amount of DNA or RNA, and therefore a limited number of genes, can fit into a virion capsid. A capsid plus the enclosed nucleic acid is called a **nucleocapsid**.

Nature has found two basic ways of arranging the multiple capsid protein subunits and the viral genome into a nucleocapsid. In some viruses, multiple copies of a single coat protein form a **helical** structure that encloses and protects the viral RNA or DNA, which runs in a helical groove within the protein tube. Viruses with such a helical nucleocapsid, such as tobacco mosaic virus, have a rodlike shape (Figure 4-44a). The other major structural type is based on the **icosahedron**, a solid, approximately spherical object built of 20 identical faces, each of which is an equilateral triangle (Figure 4-44b). During infection, some icosahedral viruses interact with host cell-surface receptors via clefts in between the capsid subunits, others interact via long fiberlike proteins extending from the nucleocapsid.

In many DNA bacteriophages, the viral DNA is located within an icosahedral “head” that is attached to a rodlike “tail.” During infection, viral proteins at the tip of the tail bind to host-cell receptors, and then the viral DNA passes down the tail into the cytoplasm of the host cell (Figure 4-44c).

In some viruses, the symmetrically arranged nucleocapsid is covered by an external membrane, or **envelope**, which consists mainly of a phospholipid bilayer but also contains one or two types of virus-encoded glycoproteins (Figure 4-44d). The phospholipids in the viral envelope are similar to those in the plasma membrane of an infected host cell. The viral envelope is, in fact, derived by budding from that membrane, but contains mainly viral glycoproteins, as we will discuss shortly.

Viruses Can Be Cloned and Counted in Plaque Assays

The number of infectious viral particles in a sample can be quantified by a **plaque assay**. This assay is performed by culturing a dilute sample of viral particles on a plate covered with host cells and then counting the number of local lesions, called **plaques**, that develop (Figure 4-45). A plaque develops on the plate wherever a single virion initially infects a single cell. The virus replicates in this initial host cell and then lyses (ruptures) the cell, releasing many progeny virions that infect the neighboring cells on the plate. After a few such cycles of infection, enough cells are lysed to produce a visible clear area, or plaque, in the layer of remaining uninfected cells.

Since all the progeny virions in a plaque are derived from a single parental virus, they constitute a **virus clone**. This type of plaque assay is in standard use for bacterial and animal viruses. Plant viruses can be assayed similarly by counting local lesions on plant leaves inoculated with viruses. Analysis of viral mutants, which are commonly isolated by

Tobacco mosaic virus

Baker; Part (c): Dept. of Microbiology, Biozentrum/Science Photo Library; Part (d) : James Cavallini/Photo Researchers, Inc.]

plaque assays, has contributed extensively to our current understanding of molecular cellular processes.

Lytic Viral Growth Cycles Lead to Death of Host Cells

Although details vary among different types of viruses, those that exhibit a *lytic cycle* of growth proceed through the following general stages:

1. Adsorption—Virion interacts with a host cell by binding of multiple copies of capsid protein to specific receptors on the cell surface.

2. Penetration—Viral genome crosses the plasma membrane. For some viruses, viral proteins packaged inside the capsid also enter the host cell.

3. Replication—Viral mRNAs are produced with the aid of the host-cell transcription machinery (DNA viruses) or by viral enzymes (RNA viruses). For both types of viruses, viral mRNAs are translated by the host-cell translation machinery. Production of multiple copies of the viral genome is carried out either by viral proteins alone or with the help of host-cell proteins.

4. Assembly—Viral proteins and replicated genomes associate to form progeny virions.

EXPERIMENTAL FIGURE 4-45 Plaque assay. The plaque assay determines the number of infectious particles in a viral suspension. (a) Each lesion, or plaque, which develops where a single virion initially infected a single cell, constitutes a pure viral clone. (b) Plaques on a lawn of *Pseudomonas fluorescens* bacteria made by bacteriophage Φ S1. [Part (b) Courtesy of Dr. Pierre ROSSI, Ecole Polytechnique fédérale de Lausanne (LBE-EPFL).]

5. Release—Infected cell either ruptures suddenly (lysis), releasing all the newly formed virions at once, or disintegrates gradually, with slow release of virions. Both cases lead to the death of the infected cell.

Figure 4-46 illustrates the lytic cycle for T4 bacteriophage, a nonenveloped DNA virus that infects *E. coli*. Viral capsid proteins generally are made in large amounts because many copies of them are required for the assembly of each progeny virion. In each infected cell, about 100–200 T4 progeny virions are produced and released by lysis.

The lytic cycle is somewhat more complicated for DNA viruses that infect eukaryotic cells. In most such viruses, the DNA genome is transported (with some associated proteins) into the cell nucleus. Once inside the nucleus, the viral DNA is transcribed into RNA by the host's transcription machinery.

FIGURE 4-46 Lytic replication cycle of a nonenveloped, bacterial virus. *E. coli* bacteriophage T4 has a double-stranded DNA genome and lacks a membrane envelope. After viral coat proteins at the tip of the tail in T4 interact with specific receptor proteins on the exterior of the host cell, the viral genome is injected into the host (step 1). Host-cell enzymes then transcribe viral "early" genes into mRNAs and subsequently translate these into viral "early" proteins (step 2). The early proteins replicate the viral DNA and induce expression of viral "late" proteins by host-cell enzymes (step 3). The viral late proteins include capsid and assembly proteins and enzymes that degrade the host-cell DNA, supplying nucleotides for synthesis of more viral DNA. Progeny virions are assembled in the cell (step 4) and released (step 5) when viral proteins lyse the cell. Newly liberated viruses initiate another cycle of infection in other host cells.

Processing of the viral RNA primary transcript by host-cell enzymes yields viral mRNA, which is transported to the cytoplasm and translated into viral proteins by host-cell ribosomes, tRNA, and translation factors. The viral proteins are then transported back into the nucleus, where some of them either replicate the viral DNA directly or direct cellular proteins to replicate the viral DNA, as in the case of SV40 discussed in an earlier section. Assembly of the capsid proteins with the newly replicated viral DNA occurs in the nucleus, yielding thousands to hundreds of thousands of progeny virions.

Most plant and animal viruses with an RNA genome do not require nuclear functions for lytic replication. In some of these viruses, a virus-encoded enzyme that enters the host during penetration transcribes the genomic RNA into mRNAs in the cell cytoplasm. The mRNA is directly translated into viral proteins by the host-cell translation machinery. One or more of these proteins then produces additional copies of the viral RNA genome. Finally, progeny genomes are assembled with newly synthesized capsid proteins into progeny virions in the cytoplasm.

FIGURE 4-47 Lytic replication cycle of an enveloped animal virus. Rabies virus is an enveloped virus with a single-stranded RNA genome. The structural components of this virus are depicted at the top. After a virion adsorbs to multiple copies of a specific host membrane protein (step **1**), the cell engulfs it in an endosome (step **2**). A cellular protein in the endosome membrane pumps H^+ ions from the cytosol into the endosome interior. The resulting decrease in endosomal pH induces a conformational change in the viral glycoprotein, leading to fusion of the viral envelope with the endosomal lipid bilayer membrane and release of the nucleocapsid into the cytosol (steps **3** and **4**). Viral RNA polymerase uses ribonucleoside triphosphates in the cytosol to replicate the viral RNA genome (step **5**) and to synthesize viral mRNAs (step **6**). One of the viral mRNAs encodes the viral transmembrane glycoprotein, which is inserted into the membrane

of the endoplasmic reticulum (ER) as it is synthesized on ER-bound ribosomes (step **7**). Carbohydrate is added to the large folded domain inside the ER lumen and is modified as the membrane and the associated glycoprotein pass through the Golgi apparatus (step **8**). Vesicles with mature glycoprotein fuse with the host plasma membrane, depositing viral glycoprotein on the cell surface with the large receptor-binding domain outside the cell (step **9**). Meanwhile, other viral mRNAs are translated on host-cell ribosomes into nucleocapsid protein, matrix protein, and viral RNA polymerase (step **10**). These proteins are assembled with replicated viral genomic RNA (bright red) into progeny nucleocapsids (step **11**), which then associate with the cytosolic domain of viral transmembrane glycoproteins in the plasma membrane (step **12**). The plasma membrane is folded around the nucleocapsid, forming a "bud" that eventually is released (step **13**).

After the synthesis of hundreds to hundreds of thousands of new virions has been completed, depending on the type of virus and host cell, most infected bacterial cells and some infected plant and animal cells are lysed, releasing all the virions at once. In many plant and animal viral infections, however, no discrete lytic event occurs; rather, the dead host cell releases the virions as it gradually disintegrates.

As noted previously, enveloped animal viruses are surrounded by an outer phospholipid bilayer derived from the plasma membrane of host cells and containing abundant viral glycoproteins. The processes of adsorption and release of enveloped viruses differ substantially from these processes

for nonenveloped viruses. To illustrate lytic replication of enveloped viruses, we consider the rabies virus, whose nucleocapsid consists of a single-stranded RNA genome surrounded by multiple copies of nucleocapsid protein. Like other lytic RNA viruses, rabies virions are replicated in the cytoplasm and do not require host-cell nuclear enzymes. As shown in Figure 4-47, a rabies virion is adsorbed by endocytosis, and release of progeny virions occurs by *budding* from the host-cell plasma membrane. Budding virions are clearly visible in electron micrographs of infected cells, as illustrated in Figure 4-48. Many tens of thousands of progeny virions bud from an infected host cell before it dies.

EXPERIMENTAL FIGURE 4-48 Release of progeny virions by budding. Progeny virions of enveloped viruses are released by budding from infected cells. In this transmission electron micrograph of a cell infected with measles virus, virion buds are clearly visible protruding from the cell surface. Measles virus is an enveloped RNA virus with a helical nucleocapsid, like rabies virus, and replicates as illustrated in Figure 4-47. [From A. Levine, 1991, *Viruses*, Scientific American Library, p. 22.]

Viral DNA Is Integrated into the Host-Cell Genome in Some Nonlytic Viral Growth Cycles

Some bacterial viruses, called *temperate phages*, can establish a nonlytic association with their host cells that does not kill the cell. For example, when bacteriophage λ infects *E. coli*, most of the time it causes a lytic infection. Occasionally, however, the viral DNA is integrated into the host-cell chromosome rather than being replicated. The integrated viral DNA, called a *prophage*, is replicated as part of the cell's DNA from one host-cell generation to the next. This phenomenon is referred to as **lysogeny**. If the host cell suffers extensive damage to its DNA from ultraviolet light, the prophage DNA is activated, leading to its excision from the host-cell chromosome, entrance into the lytic cycle, and subsequent production and release of progeny virions before the host cell dies.

The genomes of a number of animal viruses also can integrate into the host-cell genome. Among the most important are the **retroviruses**, which are enveloped viruses with a genome consisting of two identical strands of RNA. These viruses are known as *retroviruses* because their RNA genome acts as a template for formation of a DNA molecule—the opposite flow of genetic information compared with the

more common transcription of DNA into RNA. In the retroviral life cycle (Figure 4-49), a viral enzyme called **reverse transcriptase** initially copies the viral RNA genome into single-stranded DNA complementary to the virion RNA; the same enzyme then catalyzes synthesis of a complementary DNA strand. (This complex reaction is detailed in Chapter 6 when we consider closely related intracellular parasites called retrotransposons.) The resulting double-stranded DNA is integrated into the chromosomal DNA of the infected cell. Finally, the integrated DNA, called a *provirus*, is transcribed by the cell's own machinery into RNA, which either is translated into viral proteins or is packaged within virion coat proteins to form progeny virions that are released by budding from the host-cell membrane. Because most retroviruses do not kill their host cells, infected cells can replicate, producing daughter cells with integrated proviral DNA. These daughter cells continue to transcribe the proviral DNA and bud progeny virions.

Some retroviruses contain cancer-causing genes (**oncogenes**), and cells infected by such retroviruses are **oncogenically transformed** into tumor cells. Studies of oncogenic retroviruses (mostly viruses of birds and mice) have revealed a great deal about the processes that lead to transformation of a normal cell into a cancer cell (Chapter 24).

Among the known human retroviruses are human T-cell lymphotropic virus (HTLV), which causes a form of leukemia, and human immunodeficiency virus (HIV-1), which causes acquired immune deficiency syndrome (AIDS). Both of these viruses can infect only specific cell types, primarily certain cells of the immune system and, in the case of HIV-1, some central nervous system neurons and glial cells. Only these cells have cell-surface receptors that interact with viral envelope proteins, accounting for the host-cell specificity of these viruses. Unlike most other retroviruses, HIV-1 eventually kills its host cells. The eventual death of large numbers of immune-system cells results in the defective immune response characteristic of AIDS.

Some DNA viruses also can integrate into a host-cell chromosome. One example is the human papillomaviruses (HPVs), which most commonly cause warts and other benign skin lesions. The genomes of certain HPV serotypes, however, occasionally integrate into the chromosomal DNA of infected cervical epithelial cells, initiating development of cervical cancer. Routine Pap smears can detect cells in the early stages of the transformation process initiated by HPV integration, permitting effective treatment before cancer develops. A vaccine for the types of HPV associated with cervical cancer has been developed and can protect against the initial infection by these viruses, and consequently, against development of cervical cancer. However, once an individual is infected with these HPVs, the “window of opportunity” is missed, and the vaccine does not protect against the development of cancer. Because the vaccine is not 100 percent effective, even vaccinated women should have regular Pap smears. ■

OVERVIEW ANIMATION: Life Cycle of a Retrovirus

FIGURE 4-49 Retroviral life cycle. Retroviruses have a genome of two identical copies of single-stranded RNA and an outer envelope. Step **1**: After viral glycoproteins in the envelope interact with a specific host-cell membrane protein, the retroviral envelope fuses directly with the plasma membrane, allowing entry of the nucleocapsid into the cytoplasm of the cell. Step **2**: Viral reverse transcriptase and other proteins copy the viral ssRNA genome into a double-stranded DNA. Step **3**: The viral dsDNA is transported into the nucleus and integrated

into one of many possible sites in the host-cell chromosomal DNA. For simplicity, only one host-cell chromosome is depicted. Step **4**: The integrated viral DNA (provirus) is transcribed by the host-cell RNA polymerase, generating mRNAs (dark red) and genomic RNA molecules (bright red). The host-cell machinery translates the viral mRNAs into glycoproteins and nucleocapsid proteins. Step **5**: Progeny virions then assemble and are released by budding as illustrated in Figure 4-47.

KEY CONCEPTS of Section 4.7

Viruses: Parasites of the Cellular Genetic System

- Viruses are small parasites that can replicate only in host cells. Viral genomes may be either DNA (DNA viruses) or RNA (RNA viruses) and either single- or double-stranded.
- The capsid, which surrounds the viral genome, is composed of multiple copies of one or a small number of virus-encoded proteins. Some viruses also have an outer envelope, which is similar to the plasma membrane but contains viral transmembrane proteins.
- Most animal and plant DNA viruses require host-cell nuclear enzymes to carry out transcription of the viral genome into mRNA and production of progeny genomes. In contrast, most RNA viruses encode enzymes that can transcribe the RNA genome into viral mRNA and produce new copies of the RNA genome.
- Host-cell ribosomes, tRNAs, and translation factors are used in the synthesis of all viral proteins in infected cells.

- Lytic viral infection entails adsorption, penetration, synthesis of viral proteins and progeny genomes (replication), assembly of progeny virions, and release of hundreds to thousands of virions, leading to death of the host cell (see Figure 4-46). Release of enveloped viruses occurs by budding through the host-cell plasma membrane (see Figure 4-47).
- Nonlytic infection occurs when the viral genome is integrated into the host-cell DNA and generally does not lead to cell death.
- Retroviruses are enveloped animal viruses containing a single-stranded RNA genome. After a host cell is penetrated, reverse transcriptase, a viral enzyme carried in the virion, converts the viral RNA genome into double-stranded DNA, which integrates into chromosomal DNA (see Figure 4-49).
- Unlike infection by other retroviruses, HIV infection eventually kills host cells, causing the defects in the immune response characteristic of AIDS.

- Tumor viruses, which contain oncogenes, may have an RNA genome (e.g., human T-cell lymphotropic virus) or a DNA genome (e.g., human papillomaviruses). In the case of these viruses, integration of the viral genome into a host-cell chromosome can cause transformation of the cell into a tumor cell.

Perspectives for the Future

The basic cellular molecular genetic processes discussed in this chapter form the foundation of contemporary molecular cell biology. Our current understanding of these processes is grounded in a wealth of experimental results and is not likely to change. However, the depth of our understanding will continue to increase as additional details of the structures and interactions of the macromolecular machines involved are uncovered. The determination in recent years of the three-dimensional structures of RNA polymerases, ribosomal subunits, and DNA replication proteins has allowed researchers to design ever more penetrating experimental approaches for revealing how these macromolecules operate at the molecular level. The detailed level of understanding currently being developed may allow the design of new and more effective drugs for treating illnesses of humans, crops, and livestock. For example, the recent high-resolution structures of ribosomes are providing insights into the mechanism by which antibiotics inhibit bacterial protein synthesis without affecting the function of mammalian ribosomes. This new knowledge may allow the design of even more effective antibiotics. Similarly, detailed understanding of the mechanisms regulating transcription of specific human genes may lead to therapeutic strategies that can reduce or prevent inappropriate immune responses that lead to multiple sclerosis and arthritis, the inappropriate cell division that is the hallmark of cancer, and other pathological processes.

Much of current biological research is focused on discovering how molecular interactions endow cells with decision-making capacity and their special properties. For this reason, several of the following chapters describe current knowledge about how such interactions regulate transcription and protein synthesis in multicellular organisms and how such regulation endows cells with the capacity to perform their specialized functions. Other chapters deal with how protein-protein interactions underlie the construction of specialized organelles in cells, and how they determine cell shape and movement. The rapid advances in molecular cell biology in recent years hold promise that in the not too distant future we will understand more deeply how the regulation of specialized cell function, shape, and mobility, coupled with regulated cell replication and cell death (apoptosis), lead to the growth of complex organisms such as flowering plants and human beings.

Key Terms

anticodon 131	Okazaki fragments 147
codon 131	phosphodiester bond 118
complementary 119	polyribosome 142
crossing over 156	primary transcript 127
deamination 152	primer 145
depurination 153	promoter 124
DNA end-joining 155	reading frame 132
DNA polymerase 145	recombination 116
double helix 118	replication fork 145
excision-repair systems 153	retroviruses 164
exon 127	reverse transcriptase 164
gene conversion 159	ribosomal RNA (rRNA) 116
genetic code 131	ribosome 131
Holliday structure 157	RNA polymerase 124
homologous recombination 157	thymine-thymine dimer 154
intron 127	transcription 116
isoform 130	transfer RNA (tRNA) 116
lagging strand 146	translation 116
leading strand 146	viral envelope 160
messenger RNA (mRNA) 116	Watson-Crick base pairs 118
mutation 151	

Review the Concepts

1. What are Watson-Crick base pairs? Why are they important?
2. Preparing plasmid (double-stranded, circular) DNA for sequencing involves annealing a complementary, short, single-stranded oligonucleotide DNA primer to one strand of the plasmid template. This is routinely accomplished by heating the plasmid DNA and primer to 90 °C and then slowly bringing the temperature down to 25 °C. Why does this protocol work?
3. What difference between RNA and DNA helps to explain the greater stability of DNA? What implications does this have for the function of DNA?
4. What are the major differences in the synthesis and structure of prokaryotic and eukaryotic mRNAs?
5. While investigating the function of a specific growth factor receptor gene from humans, researchers found that two types of proteins are synthesized from this gene. A larger protein containing a membrane-spanning domain functions to recognize growth factors at the cell surface, stimulating a specific downstream signaling pathway. In contrast, a related,

smaller protein is secreted from the cell and functions to bind available growth factor circulating in the blood, thus inhibiting the downstream signaling pathway. Speculate on how the cell synthesizes these disparate proteins.

6. The transcription of many bacterial genes relies on functional groups called *operons*, such as the tryptophan operon (Figure 4-13a). What is an operon? What advantages are there to having genes arranged in an operon, compared with the arrangement in eukaryotes?

7. How would a mutation in the poly(A)-binding protein gene affect translation? How would an electron micrograph of polyribosomes from such a mutant differ from the normal pattern?

8. What characteristic of DNA results in the requirement that some DNA synthesis is discontinuous? How are Okazaki fragments and DNA ligase utilized by the cell?

9. Eukaryotes have repair systems that prevent mutations due to copying errors and exposure to mutagens. What are the three excision-repair systems found in eukaryotes, and which one is responsible for correcting thymine-thymine dimers that form as a result of UV light damage to DNA?

10. DNA-repair systems are responsible for maintaining genomic fidelity in normal cells despite the high frequency with which mutational events occur. What type of DNA mutation is generated by (a) UV irradiation and (b) ionizing radiation? Describe the system responsible for repairing each of these types of mutations in mammalian cells. Postulate why a loss of function in one or more DNA-repair systems typifies many cancers.

11. What is the name given to the process that can repair DNA damage and generate genetic diversity? Briefly describe the similarities and differences of the two processes.

12. The genome of a retrovirus can integrate into the host-cell genome. What gene is unique to retroviruses, and why is the protein encoded by this gene absolutely necessary for maintaining the retroviral life cycle? A number of retroviruses can infect certain human cells. List two of them, briefly describe the medical implications resulting from these infections, and describe why only certain cells are infected.

13. a. Which of the following DNA strands, the top or bottom, would serve as a template for RNA transcription if the DNA molecule were to unwind in the indicated direction?

5'ACGGACTGTACCGCTGAAGTCATGGACGCTCGA 3'
3'TGCCTGACATGGCGACTTCAGTACCTGCGAGCT 5'

Direction of DNA unwinding

b. What would be the resulting RNA sequence (written 5' to 3')?

14. Contrast prokaryotic and eukaryotic gene characteristics.

15. You have learned about the events surrounding DNA replication and the central dogma. Identify the steps associated with these processes that will be adversely affected in the following scenarios.

a. Helicases unwind the DNA, but stabilizing proteins are mutated and cannot bind to the DNA.

b. The mRNA molecule forms a hairpin loop on itself via complementary base pairing in an area spanning the AUG start site.

c. The cell is unable to produce functional tRNA^{met}.

16. Use the key provided below to determine the amino acid sequence of the polypeptide produced from the following DNA sequence. Intron sequences are highlighted. Note: Not all amino acids in the key will be used.

5' TTCTAAACGCATGAAGCACCGTCTCAGAGCCAGTGA 3'
3' AAGATTTGCGTACTTCGTGGCAGAGTCTCGGTCCT 5'

Direction of DNA unwinding

Asn = AAU Cys = TCG Gly = CAG His = CAU Lys = AAG

Met = AUG Phe = UUC Ser = AGC Tyr = UAC Val = GUC; GUA

17. a. Look at the figure above. Explain why it is necessary for Okazaki fragments to be formed as the lagging strand is produced (instead of a continuous strand).

b. If the DNA polymerase in the figure above could only bind to the lower template strand, under what condition(s) would it be able to produce a leading strand?

18. The DNA repair systems preferentially target the newly synthesized strand. Why is this important?

19. Identify the specific types of point mutations below (you are viewing the direct DNA version of the RNA sequence).

Original sequence: 5' AUG TCA GGA CGT CAC TCA GCT 3'

Mutation A: 5' AUG TCA GGA CGT CAC TGA GCT 3'

Mutation B: 5' AUA TCA GGA CGT CAC TCA GCT 3'

20. a. Detail the key differences between lytic and nonlytic viral infection and provide an example of each.

b. Which of the following processes occurs in both lytic and nonlytic viral infections?

(i) Infected cell ruptures to release viral particles.

(ii) Viral mRNAs are transcribed by the host-cell translation machinery.

(iii) Viral proteins and nucleic acids are packaged to produce virions.

Analyze the Data

Protein synthesis in eukaryotes normally begins at the first AUG codon in the mRNA. Sometimes, however, the ribosomes do not begin protein synthesis at this first AUG but scan past it (leaky scanning), and protein synthesis begins instead at an internal AUG. In order to understand what features of an mRNA affect efficiency of initiation at the first AUG, studies have been undertaken in which the synthesis of chloramphenicol acetyltransferase was examined. Translation of its message can give rise to a protein referred to as preCAT or give rise to a slightly smaller protein, CAT (see M. Kozak, 2005, *Gene* 361:13). The two proteins differ in that CAT lacks several amino acids found at the N-terminus of preCAT. CAT is not derived by cleavage of preCAT but, instead, by initiation of translation of the mRNA at an internal AUG:

a. Results from a number of studies have given rise to the hypothesis that the sequence (−3)ACCAUGG(+4), in which the start codon AUG is shown in boldface, provides an optimal context for initiation of protein synthesis and ensures that ribosomes do not scan past this first AUG to begin initiation instead at a downstream AUG. In the numbering scheme used here, the A of the AUG initiation is designated (11); bases 5′ of this are given negative numbers [so that the first base of this sequence is (−3)], and bases 3′ to the (+1) A are given positive numbers [so that the last base of this sequence is (+4)]. To test the hypothesis that the start site sequence (−3)ACCAUGG(+4) prevents leaky scanning, the chloramphenicol acetyltransferase mRNA sequence was modified and the resulting effects on translation assessed. In the following figure, the sequence (red) surrounding the first AUG codon (black) of the mRNA that gives rise to the synthesis of preCAT is shown above lane 3. Modification of this message is shown above the other gel lanes (altered nucleotides are in blue), and the completed proteins generated from each modified message appear as bands on the SDS-polyacrylamide gel below. The intensity of each band is an indication of the amount of that protein synthesized. Analyze the alterations to the wild-type sequence, and describe how they affect translation. Are the positions of some nucleotides more important than others? Do the data shown in this figure provide support for the hypothesis that the context in which the first AUG is present affects efficiency of translation from this site? Is ACCAUGG an optimal context for initiation from the first AUG?

b. What are some additional alterations to this message, other than those shown in the figure, that would further elucidate the importance of the ACCAUGG sequence as an optimal context for synthesis of preCAT rather than CAT? How would you further examine whether A at the (−3) position and G at the (+4) position are the most important nucleotides to provide context for the AUG start?

c. A mutation causing a severe blood disease has been found in a single family (see T. Matthes et al., 2004, *Blood* 104:2181). The mutation, shown in red in the figure below, has been mapped to the 5′-untranslated region of the gene encoding hepcidin and has been found to alter the gene's mRNA. The shaded regions indicate the coding sequence of the normal and mutant genes. No hepcidin is produced from the altered mRNA, and lack of hepcidin results in the disease. Can you provide a reasonable explanation for the lack of synthesis of hepcidin in the family members who have inherited this mutation? What can you deduce about the importance of the context in which the start site for initiation of protein synthesis occurs in this case?

The Planarian is a freshwater flatworm with an amazing capacity for regeneration. If the head and tail of an adult Planarian are sliced off, the worm will readily regenerate these structures (as shown in the upper left frame). The role of specific genes in the regeneration process can be tested by shutting off gene expression by RNA interference (RNAi) before cutting off the head and tail. The remaining eight frames show the variety of regeneration defects that can be observed after RNAi of different genes responsible for regeneration. The genes inhibited by RNAi are from left to right starting at the upper center panel are: *smad4*, β -catenin-1, carcinoma antigen, POU2/3, rootletin, Novel, tolloid, and *piwi*. [Courtesy of Peter Reddien/MIT, Whitehead Institute.]

In the field of molecular cell biology, reduced to its most basic elements, we seek an understanding of the biological behavior of cells in terms of the underlying chemical and molecular mechanisms. Often the investigation of a new molecular process focuses on the function of a particular protein. There are three fundamental questions that cell biologists usually ask about a newly discovered protein: what is the function of the protein in the context of a living cell, what is the biochemical function of the purified protein, and where is the protein located? To answer these questions, investigators employ three molecular genetic tools: the gene that encodes the protein, a mutant cell line or organism that lacks the functional protein, and a source of the purified protein for biochemical studies. In this chapter, we consider various aspects of two basic experimental strategies for obtaining all three tools (Figure 5-1).

The first strategy, often referred to as *classical genetics*, begins with isolation of a mutant that appears to be defective in some process of interest. Genetic methods then are used to identify and isolate the affected gene. The isolated gene can be manipulated to produce large quantities of the protein for biochemical experiments and to design probes for studies of

Molecular Genetic Techniques

where and when the encoded protein is expressed in an organism. The second strategy follows essentially the same steps as the classical approach but in reverse order, beginning with isolation of an interesting protein or its identification based on analysis of an organism's genomic sequence. Once the corresponding gene has been isolated, the gene can be altered and then reinserted into an organism. In both strategies, by examining the phenotypic consequences of mutations that inactivate a particular gene, geneticists are able to connect knowledge about the sequence, structure, and biochemical activity of the encoded protein to its function in the context of a living cell or multicellular organism.

An important component in both strategies for studying a protein and its biological function is isolation of the corresponding gene. Thus we discuss various techniques by which researchers can isolate, sequence, and manipulate specific regions of an organism's DNA. Next we introduce a variety of techniques that are commonly used to analyze where and when a particular gene is expressed and where in the cell its protein is localized. In some cases, knowledge of protein function can lead to significant medical advances, and the first step in developing treatments for an inherited disease is

5.5	Inactivating the Function of Specific Genes in Eukaryotes	212

FIGURE 5-1 Overview of two strategies for relating the function, location, and structure of gene products. A mutant organism is the starting point for the classical genetic strategy (green arrows). The reverse strategy (orange arrows) usually begins with identification of a protein-coding sequence by analysis of genome-sequence databases. In both strategies, the actual gene is isolated either from a DNA library or by specific amplification of the gene sequence from genomic DNA. Once a cloned gene is isolated, it can be used to produce the encoded protein in bacterial or eukaryotic expression systems. Alternatively, a cloned gene can be inactivated by one of various techniques and used to generate mutant cells or organisms.

to identify and isolate the affected gene, which we describe here. Finally, we discuss techniques that abolish normal protein function in order to analyze the role of the protein in the cell.

5.1 Genetic Analysis of Mutations to Identify and Study Genes

As described in Chapter 4, the information encoded in the DNA sequence of genes specifies the sequence—and therefore the structure and function—of every protein molecule in a cell. The power of genetics as a tool for studying cells and organisms lies in the ability of researchers to selectively alter every copy of just one type of protein in a cell by making a change in the gene for that protein. Genetic analyses of mutants defective in a particular process can reveal (a) new genes required for the process to occur, (b) the order in which gene products act in the process, and (c) whether the proteins encoded by different genes interact with one another. Before seeing how genetic studies of this type can provide insights into the mechanism of a complicated cellular or developmental process, we first explain some basic genetic terms used throughout our discussion.

The different forms, or variants, of a gene are referred to as **alleles**. Geneticists commonly refer to the numerous naturally occurring genetic variants that exist in populations, particularly human populations, as alleles. The term **mutation** usually is reserved for instances in which an allele is known to have been newly formed, such as after treatment of an experimental organism with a **mutagen**, an agent that causes a heritable change in the DNA sequence.

Strictly speaking, the particular set of alleles for all the genes carried by an individual is its **genotype**. However, this term also is used in a more restricted sense to denote just the alleles of the particular gene or genes under examination. For experimental organisms, the term **wild type** often is used

to designate a standard genotype for use as a reference in breeding experiments. Thus the normal, nonmutant allele will usually be designated as the wild type. Because of the enormous naturally occurring allelic variation that exists in human populations, the term *wild type* usually denotes an allele that is present at a much higher frequency than any of the other possible alternatives.

Geneticists draw an important distinction between the **genotype** and the **phenotype** of an organism. The phenotype refers to all the physical attributes or traits of an individual that are the consequence of a given genotype. In practice, however, the term *phenotype* often is used to denote the physical consequences that result from just the alleles that are under experimental study. Readily observable phenotypic characteristics are critical in the genetic analysis of mutations.

Recessive and Dominant Mutant Alleles Generally Have Opposite Effects on Gene Function

A fundamental genetic difference between experimental organisms is whether their cells carry a single set of chromosomes or two copies of each chromosome. The former are referred to as haploid; the latter as diploid. Complex multicellular organisms (e.g., fruit flies, mice, humans) are diploid, whereas many simple unicellular organisms are haploid. Some organisms, notably the yeast *Saccharomyces cerevisiae*, can exist in either haploid or diploid states. The normal cells of some organisms, both plants and animals, carry more than two copies of each chromosome and are thus designated polyploid. Moreover, cancer cells begin as diploid cells but through the process of transformation into cancer cells can gain extra copies of one or more chromosomes and are thus designated as aneuploid. However, our discussion of genetic techniques and analysis relates to diploid organisms, including diploid yeasts.

DIPLOID GENOTYPE					
DIPLOID PHENOTYPE	Wild type	Mutant	Mutant	Wild type	Mutant

FIGURE 5-2 Effects of dominant and recessive mutant alleles on phenotype in diploid organisms. A single copy of a dominant allele is sufficient to produce a mutant phenotype, whereas both copies

of a recessive allele must be present to cause a mutant phenotype. Recessive mutations usually cause a loss of function; dominant mutations usually cause a gain of function or an altered function.

Although many different alleles of a gene might occur in different organisms in a population, any individual diploid organism will carry two copies of each gene and thus at most can have two different alleles. An individual with two different alleles is **heterozygous** for a gene, whereas an individual that carries two identical alleles is **homozygous** for a gene. A **recessive** mutant allele is defined as one in which both alleles must be mutant in order for the mutant phenotype to be observed; that is, the individual must be homozygous for the mutant allele to show the mutant phenotype. In contrast, the phenotypic consequences of a **dominant** mutant allele can be observed in a heterozygous individual carrying one mutant and one wild-type allele (Figure 5-2).

Whether a mutant allele is recessive or dominant provides valuable information about the function of the affected gene and the nature of the causative mutation. Recessive alleles usually result from a mutation that inactivates the affected gene, leading to a partial or complete *loss of function*. Such recessive mutations may remove part of the gene or the entire gene from the chromosome, disrupt expression of the gene, or alter the structure of the encoded protein, thereby altering its function. Conversely, dominant alleles are often the consequence of a mutation that causes some kind of *gain of function*. Such dominant mutations may increase the activity of the encoded protein, confer a new function on it, or lead to its inappropriate spatial or temporal pattern of expression.

Dominant mutations in certain genes, however, are associated with a loss of function. For instance, some genes are *haplo-insufficient*, in that removing or inactivating one of the two alleles of such a gene leads to a mutant phenotype because not enough gene product is made. In other rare instances, a dominant mutation in one allele may lead to a structural change in the protein that interferes with the function of the wild-type protein encoded by the other allele. This type of mutation, referred to as a *dominant-negative*, produces a phenotype similar to that obtained from a loss-of-function mutation.

 Some alleles can exhibit both recessive and dominant properties. In such cases, statements about whether an allele is dominant or recessive must specify the phenotype. For example, the allele of the hemoglobin gene in humans designated Hb^s has more than one phenotypic consequence. Individuals who are homozygous for this allele (Hb^s/Hb^s) have the debilitating disease sickle-cell anemia, but heterozygous individuals (Hb^s/Hb^a) do not have the disease. Therefore, Hb^s is

recessive for the trait of sickle-cell disease. On the other hand, heterozygous (Hb^s/Hb^a) individuals are more resistant to malaria than homozygous (Hb^a/Hb^a) individuals, revealing that Hb^s is *dominant* for the trait of malaria resistance. ■

A commonly used agent for inducing mutations (mutagenesis) in experimental organisms is ethylmethane sulfonate (EMS). Although this mutagen can alter DNA sequences in several ways, one of its most common effects is to chemically modify guanine bases in DNA, ultimately leading to the conversion of a G-C base pair into an A-T base pair. Such an alteration in the sequence of a gene, which involves only a single base pair, is known as a **point mutation**. A *silent* point mutation causes no change in the amino acid sequence or activity of a gene's encoded protein. However, observable phenotypic consequences due to changes in a protein's activity can arise from point mutations that result in substitution of one amino acid for another (*missense* mutation), introduction of a premature stop codon (*nonsense* mutation), or a change in the reading frame of a gene (*frameshift* mutation). Because alterations in the DNA sequence leading to a decrease in protein activity are much more likely than alterations leading to an increase or qualitative change in protein activity, mutagenesis usually produces many more recessive mutations than dominant mutations.

Segregation of Mutations in Breeding Experiments Reveals Their Dominance or Recessivity

Geneticists exploit the normal life cycle of an organism to test for the dominance or recessivity of alleles. To see how this is done, we need first to review the type of cell division that gives rise to gametes (sperm and egg cells in higher plants and animals). Whereas the body (somatic) cells of most multicellular organisms divide by mitosis, the germ cells that give rise to gametes undergo meiosis. Like somatic cells, premeiotic germ cells are diploid, containing two homologs of each morphological type of chromosome. The two homologs constituting each pair of homologous chromosomes are descended from different parents, and thus their genes may exist in different allelic forms. Figure 5-3 depicts the major events in mitotic and meiotic cell division. In mitosis, DNA replication is always followed by cell division, yielding two diploid daughter cells. In meiosis, *one* round of DNA replication is followed by *two* separate cell divisions,

MITOTIC CELL DIVISION

MEIOTIC CELL DIVISION

FIGURE 5-3 Comparison of mitosis and meiosis. Both somatic cells and premeiotic germ cells have two copies of each chromosome ($2n$), one maternal and one paternal. In mitosis, the replicated chromosomes, each composed of two sister chromatids, align at the cell center in such a way that both daughter cells receive a maternal and paternal homolog of each morphological type of chromosome. During the first *meiotic* division, however, each replicated chromosome pairs with its homologous partner at the cell center; this pairing off is referred to as *synapsis*, and crossing over between homologous chromosomes is evident at this stage. One replicated chromosome

of each morphological type then goes into each daughter cell. The resulting cells undergo a second division without intervening DNA replication, with the sister chromatids of each morphological type being apportioned to the daughter cells. In the second meiotic division the alignment of chromatids and their equal segregation into daughter cells is the same as in mitotic division. The alignment of pairs of homologous chromosomes in metaphase I is random with respect to other chromosome pairs, resulting in a mix of paternally and maternally derived chromosomes in each daughter cell.

(a) Segregation of **dominant** mutation

(b) Segregation of **recessive** mutation

FIGURE 5-4 Segregation patterns of dominant and recessive mutations in crosses between true-breeding strains of diploid organisms. All the offspring in the first (F₁) generation are heterozygous. If the mutant allele is dominant, the F₁ offspring will exhibit the mutant phenotype, as in part (a). If the mutant allele is recessive, the F₁ offspring will exhibit the wild-type phenotype, as in part (b). Crossing of the F₁ heterozygotes among themselves also produces different segregation ratios for dominant and recessive mutant alleles in the F₂ generation.

yielding four haploid (1n) cells that contain only one chromosome of each homologous pair. The apportionment, or **segregation**, of the replicated homologous chromosomes to daughter cells during the first meiotic division is random; that is, maternally and paternally derived homologs segregate independently, yielding daughter cells with different mixes of paternal and maternal chromosomes.

As a way to avoid unwanted complexity, geneticists usually strive to begin breeding experiments with strains that are homozygous for the genes under examination. In such *true-breeding* strains, every individual will receive the same allele from each parent and therefore the composition of alleles will not change from one generation to the next. When a true-breeding mutant strain is mated to a true-breeding wild-type strain, all the first filial (F₁) progeny will be heterozygous (Figure 5-4). If the F₁ progeny exhibit the mutant trait, then the mutant allele is dominant; if the F₁ progeny exhibit the wild-type trait, then the mutant is recessive. Further crossing between F₁ individuals will also reveal different patterns of inheritance according to whether the mutation is dominant or recessive. When F₁ individuals that are heterozygous for a dominant allele are crossed among themselves, three-fourths of the resulting F₂ progeny will exhibit the mutant trait. In contrast, when F₁ individuals that are heterozygous for a recessive allele are crossed among themselves, only one-fourth of the resulting F₂ progeny will exhibit the mutant trait.

As noted earlier, the yeast *S. cerevisiae*, an important experimental organism, can exist in either a haploid or a diploid state. In these unicellular eukaryotes, crosses between haploid cells can determine whether a mutant allele is dominant or recessive. Haploid yeast cells, which carry one copy of each chromosome, can be of two different mating types known as a and α. Haploid cells of opposite mating type can mate to produce a/α diploids, which carry two copies of each chromosome. If a new mutation with an observable phenotype is isolated in a haploid strain, the mutant strain can be mated to a wild-type strain of the opposite mating type to produce a/α diploids that are heterozygous for the mutant allele. If these diploids exhibit the mutant trait, then the mutant allele is dominant, but if the diploids appear as wild type, then the mutant allele is recessive. When a/α diploids are placed under starvation conditions, the cells undergo meiosis, giving rise to a tetrad of four haploid spores, two of type a and two of type α. Sporulation of a heterozygous diploid cell yields two spores carrying the mutant allele and two carrying the wild-type allele (Figure 5-5). Under appropriate conditions, yeast spores will germinate, producing vegetative haploid strains of both mating types.

Conditional Mutations Can Be Used to Study Essential Genes in Yeast

The procedures used to identify and isolate mutants, referred to as *genetic screens*, depend on whether the experimental organism is haploid or diploid and, if the latter, whether the mutation is recessive or dominant. Genes that encode pro-

FIGURE 5-5 Segregation of alleles in yeast. (a) Haploid *Saccharomyces* cells of opposite mating type (i.e., one of mating type α and one of mating type a) can mate to produce an α/α diploid. If one haploid carries a dominant wild-type allele and the other carries a recessive mutant allele of the same gene, the resulting heterozygous diploid will express the dominant trait. Under certain conditions, a diploid cell will form a tetrad of four haploid spores. Two of the spores in the tetrad will express the recessive trait and two will express the dominant trait. (b) If the mutant phenotype is not viable under restrictive growth conditions, each tetrad, shown here as four spores separated vertically and grown into colonies on restrictive media, consists of two viable and two nonviable spores. [Part (b) from B. Senger et al., 1998, *EMBO J* 17:2196]

teins essential for life are among the most interesting and important ones to study. Since phenotypic expression of mutations in essential genes leads to death of the individual, clever genetic screens are needed to isolate and maintain organisms with a lethal mutation.

In haploid yeast cells, essential genes can be studied through the use of *conditional mutations*. Among the most common conditional mutations are **temperature-sensitive mutations**, which can be isolated in bacteria and lower eukaryotes but not in warm-blooded eukaryotes. For instance, a single missense mutation may cause the resulting mutant protein to have reduced thermal stability such that the protein is fully functional at one temperature (e.g., 23 °C) but begins to denature and is inactive at another temperature (e.g., 36 °C), whereas the normal protein would be fully stable and functional at both temperatures. A temperature at which the mu-

tant phenotype is observed is called *nonpermissive*; a *permissive* temperature is one at which the mutant phenotype is not observed even though the mutant allele is present. Thus mutant strains can be maintained at a permissive temperature and then subcultured at a nonpermissive temperature for analysis of the mutant phenotype.

An example of a particularly important screen for temperature-sensitive mutants in the yeast *S. cerevisiae* comes from the studies of L. H. Hartwell and colleagues in the late 1960s and early 1970s. They set out to identify genes important in regulation of the cell cycle during which a cell synthesizes proteins, replicates its DNA, and then undergoes mitotic cell division, with each daughter cell receiving a copy of each chromosome. Exponential growth of a single yeast cell for 20–30 cell divisions forms a visible yeast colony on solid agar medium. Since mutants with a complete block in the cell cycle would not be able to form a colony, conditional mutants were required to study mutations that affect this basic cell process. To screen for such mutants, the researchers first identified mutagenized yeast cells that could grow normally at 23 °C but that could not form a colony when placed at 36 °C (Figure 5-6a).

Once temperature-sensitive mutants were isolated, further analysis revealed that some indeed were defective in cell division. In *S. cerevisiae*, cell division occurs through a budding process, and the size of the bud, which is easily visualized by light microscopy, indicates a cell's position in the cell cycle. Each of the mutants that could not grow at 36 °C was examined by microscopy after several hours at the nonpermissive temperature. Examination of many different temperature-sensitive mutants revealed that about 1 percent exhibited a distinct block in the cell cycle. These mutants were therefore designated *cdc* (cell division cycle) mutants. Importantly, these yeast mutants did not simply fail to grow, as they might if they carried a mutation affecting general cellular metabolism. Rather, at the nonpermissive temperature, the mutants of interest grew normally for part of the cell cycle but then arrested at a particular stage of the cell cycle, so that many cells at this stage were seen (Figure 5-6b). Most *cdc* mutations in yeast are recessive; that is, when haploid *cdc* strains are mated to wild-type haploids, the resulting heterozygous diploids are neither temperature sensitive nor defective in cell division.

Recessive Lethal Mutations in Diploids Can Be Identified by Inbreeding and Maintained in Heterozygotes

In diploid organisms, phenotypes resulting from recessive mutations can be observed only in individuals homozygous for the mutant alleles. Since mutagenesis in a diploid organism typically changes only one allele of a gene, yielding heterozygous mutants, genetic screens must include inbreeding steps to generate progeny that are homozygous for the mutant alleles. The geneticist H. Muller developed a general and efficient procedure for carrying out such inbreeding experiments in the

(b) Wild type

cdc28 mutants

cdc7 mutants

EXPERIMENTAL FIGURE 5-6 Haploid yeasts carrying temperature-sensitive lethal mutations are maintained at permissive temperature and analyzed at nonpermissive temperature. (a) Genetic screen for temperature-sensitive cell-division cycle (*cdc*) mutants in yeast. Yeasts that grow and form colonies at 23 °C (permissive temperature) but not at 36 °C (nonpermissive temperature) may carry a lethal mutation that blocks cell division. (b) Assay of temperature-sensitive colonies for blocks at specific stages in the cell cycle. Shown here are micrographs of wild-type yeast and two different temperature-sensitive mutants after incubation at the nonpermissive temperature for 6 h. Wild-type cells, which continue to grow, can be seen with all different sizes of buds, reflecting different stages of the cell cycle. In contrast, cells in the lower two micrographs exhibit a block at a specific stage in the cell cycle. The *cdc28* mutants arrest at a point before emergence of a new bud and therefore appear as unbudded cells. The *cdc7* mutants, which arrest just before separation of the mother cell and bud (emerging daughter cell), appear as cells with large buds. [Part (a) see L. H. Hartwell, 1967, *J. Bacteriol.* **93**:1662; part (b) from L. M. Hereford and L. H. Hartwell, 1974, *J. Mol. Biol.* **84**:445.]

fruit fly *Drosophila*. Recessive lethal mutations in *Drosophila* and other diploid organisms can be maintained in heterozygous individuals and their phenotypic consequences analyzed in homozygotes.

The Muller approach was used to great effect by C. Nüsslein-Volhard and E. Wieschaus, who systematically screened for recessive lethal mutations affecting embryogenesis in *Drosophila*. Dead homozygous embryos carrying recessive lethal mutations identified by this screen were examined under the microscope for specific morphological defects in the embryos. Current understanding of the molecular mechanisms underlying development of multicellular organisms is based, in large part, on the detailed picture of embryonic development revealed by characterization of these *Drosophila* mutants.

Complementation Tests Determine Whether Different Recessive Mutations Are in the Same Gene

In the genetic approach to studying a particular cellular process, researchers often isolate multiple recessive mutations that produce the same phenotype. A common test for determining whether these mutations are in the same gene or in different genes exploits the phenomenon of genetic complementation, that is, the restoration of the wild-type phenotype by mating of two different mutants. If two recessive mutations, *a* and *b*, are in the *same* gene, then a diploid organism heterozygous for both mutations (i.e., carrying one *a* allele and one *b* allele) will exhibit the mutant phenotype because neither allele provides a functional copy of the gene. In contrast, if mutations *a* and *b* are in *separate* genes, then heterozygotes carrying a single copy of each mutant allele will not exhibit the mutant phenotype because a wild-type allele of each gene will also be present.

In this case, the mutations are said to *complement* each other. Complementation analysis cannot be performed on dominant mutants because the phenotype conferred by the mutant allele is displayed even in the presence of a wild-type allele of the gene.

Complementation analysis of a set of mutants exhibiting the same phenotype can distinguish the individual genes in a set of functionally related genes, all of which must function to produce a given phenotypic trait. For example, the screen for *cdc* mutations in *Saccharomyces* described previously yielded many recessive temperature-sensitive mutants that appeared arrested at the same cell cycle stage. To determine how many genes were affected by these mutations, Hartwell and his colleagues performed complementation tests on all of the pair-wise combinations of *cdc* mutants following the general protocol outlined in Figure 5-7. These tests identified more than 20 different *CDC* genes. The subsequent molecular characterization of the *CDC* genes and their encoded proteins, as described in detail in Chapter 20, has provided a framework for understanding how cell

division is regulated in organisms ranging from yeast to humans.

Double Mutants Are Useful in Assessing the Order in Which Proteins Function

Based on careful analysis of mutant phenotypes associated with a particular cellular process, researchers often can deduce the order in which a set of genes and their protein products function. Two general types of processes are amenable to such analysis: (a) biosynthetic pathways in which a precursor material is converted via one or more intermediates to a final product and (b) signaling pathways that regulate other processes and involve the flow of information rather than chemical intermediates.

Ordering of Biosynthetic Pathways A simple example of the first type of process is the biosynthesis of a metabolite such as the amino acid tryptophan in bacteria. In this case, each of the enzymes required for synthesis of tryptophan catalyzes the

EXPERIMENTAL FIGURE 5-7 Complementation analysis determines whether recessive mutations are in the same or different genes. Complementation tests in yeast are performed by mating haploid *a* and α cells carrying different recessive mutations to produce diploid cells. In the analysis of *cdc* mutations, pairs of different haploid temperature-sensitive *cdc* strains were systematically mated and the resulting diploids tested for growth at the permissive and nonpermissive temperatures. In this hypothetical example, the *cdcX* and *cdcY* mutants complement each other and thus have mutations in different genes, whereas the *cdcX* and *cdcZ* mutants have mutations in the same gene.

conversion of one of the intermediates in the pathway to the next. In *E. coli*, the genes encoding these enzymes lie adjacent to one another in the genome, constituting the *trp* operon (see Figure 4-13a). The order of action of the different genes for these enzymes, hence the order of the biochemical reactions in the pathway, initially was deduced from the types of intermediate compounds that accumulated in each mutant. In the case of complex synthetic pathways, however, phenotypic analysis of mutants defective in a single step may give ambiguous results that do not permit conclusive ordering of the steps. Double mutants defective in two steps in the pathway are particularly useful in ordering such pathways (Figure 5-8a).

In Chapter 14, we discuss the classic use of the double-mutant strategy to help elucidate the secretory pathway. In this pathway, proteins to be secreted from the cell move from their site of synthesis on the rough endoplasmic reticulum (ER) to the Golgi complex, then to secretory vesicles, and finally to the cell surface.

Ordering of Signaling Pathways As we learn in later chapters, expression of many eukaryotic genes is regulated by signaling pathways that are initiated by extracellular hormones, growth factors, or other signals. Such signaling pathways may include numerous components, and double-mutant analysis often can provide insight into the functions and interactions of these components. The only prerequisite for obtaining useful information from this type of analysis is that the two mutations must have opposite effects on the output of the same regulated pathway. Most commonly, one mutation represses expression of a particular reporter gene even when the signal is present, while another mutation results in reporter gene expression even when the signal is absent (i.e., constitutive expression). As illustrated in Figure 5-8b, two simple regulatory mechanisms are consistent with such single mutants, but the double-mutant phenotype can distinguish between them. This general approach has enabled geneticists to delineate many of the key steps in a variety of different regulatory pathways, setting the stage for more specific biochemical assays.

Note that this technique differs from the complementation analysis just described in that both dominant and recessive mutants can be subjected to double-mutant analysis. When two recessive mutations are tested, the double mutant created must be *homozygous* for both mutations. Furthermore, dominant mutants can be subjected to double-mutant analysis.

Genetic Suppression and Synthetic Lethality Can Reveal Interacting or Redundant Proteins

Two other types of genetic analysis can provide additional clues about how proteins that function in the same cellular process may interact with one another in the living cell. Both of these methods, which are applicable in many experimental organisms, involve the use of double mutants in which the phenotypic effects of one mutation are changed by the presence of a second mutation.

(a) Analysis of a biosynthetic pathway

A mutation in **A** accumulates intermediate 1.

A mutation in **B** accumulates intermediate 2.

PHENOTYPE OF DOUBLE MUTANT:	A double mutation in A and B accumulates intermediate 1.
INTERPRETATION:	The reaction catalyzed by A precedes the reaction catalyzed by B.

(b) Analysis of a signaling pathway

A mutation in **A** gives repressed reporter expression.

A mutation in **B** gives constitutive reporter expression.

PHENOTYPE OF DOUBLE MUTANT:	A double mutation in A and B gives repressed reporter expression.
INTERPRETATION:	A positively regulates reporter expression and is negatively regulated by B.

PHENOTYPE OF DOUBLE MUTANT:	A double mutation in A and B gives constitutive reporter expression.
INTERPRETATION:	B negatively regulates reporter expression and is negatively regulated by A.

FIGURE 5-8 Analysis of double mutants often can order the steps in biosynthetic or signaling pathways. When mutations in two different genes affect the same cellular process but have distinctly different phenotypes, the phenotype of the double mutant can often reveal the order in which the two genes must function. (a) In the case of mutations that affect the same biosynthetic pathway, a double mutant will accumulate the intermediate immediately preceding the step catalyzed by the protein that acts earlier in the wild-type organism. (b) Double-mutant analysis of a signaling pathway is possible if two mutations have opposite effects on expression of a reporter gene. In this case, the observed phenotype of the double mutant provides information about the order in which the proteins act and whether they are positive or negative regulators.

Suppressor Mutations The first type of analysis is based on *genetic suppression*. To understand this phenomenon, suppose that point mutations lead to structural changes in one protein (A) that disrupt its ability to associate with another protein (B) involved in the same cellular process. Similarly, mutations in protein B lead to small structural changes that inhibit its ability to interact with protein A. Assume, furthermore, that the normal functioning of proteins A and B depends on their interacting. In theory, a specific structural change in protein A might be suppressed by compensatory

(a) Suppression

(b) Synthetic lethality 1

(c) Synthetic lethality 2

FIGURE 5-9 Mutations that result in genetic suppression or synthetic lethality reveal interacting or redundant proteins.

(a) Observation that double mutants with two defective proteins (A and B) have a wild-type phenotype but that single mutants give a mutant phenotype indicates that the function of each protein depends on interaction with the other. (b) Observation that double mutants have a more severe phenotypic defect than single mutants also is evidence that two proteins (e.g., subunits of a heterodimer) must interact to function normally. (c) Observation that a double mutant is nonviable but that the corresponding single mutants have the wild-type phenotype indicates that two proteins function in redundant pathways to produce an essential product.

changes in protein B, allowing the mutant proteins to interact. In the rare cases in which such suppressor mutations occur, strains carrying both mutant alleles would be normal, whereas strains carrying only one or the other mutant allele would have a mutant phenotype (Figure 5-9a).

The observation of genetic suppression in yeast strains carrying a mutant actin allele (*act1-1*) and a second mutation (*sac6*) in another gene provided early evidence for a direct interaction in vivo between the proteins encoded by the two genes. Later biochemical studies showed that these two proteins—Act1 and Sac6—do indeed interact in the construction of functional actin structures within the cell.

Synthetic Lethal Mutations Another phenomenon, called *synthetic lethality*, produces a phenotypic effect opposite to

that of suppression. In this case, the deleterious effect of one mutation is greatly exacerbated (rather than suppressed) by a second mutation in a related gene. One situation in which such synthetic lethal mutations can occur is illustrated in Figure 5-9b. In this example, a heterodimeric protein is partially, but not completely, inactivated by mutations in either one of the nonidentical subunits. However, in double mutants carrying specific mutations in the genes encoding both subunits, little interaction between subunits occurs, resulting in severe phenotypic effects. Synthetic lethal mutations also can reveal nonessential genes whose encoded proteins function in redundant pathways for producing an essential cell component. As depicted in Figure 5-9c, if either pathway alone is inactivated by a mutation, the other pathway will be able to supply the needed product. However, if both pathways are inactivated at the same time, the essential product cannot be synthesized and the double mutants will be nonviable.

Genes Can Be Identified by Their Map Position on the Chromosome

The preceding discussion of genetic analysis illustrates how a geneticist can gain insight into gene function by observing the phenotypic effects produced by joining together different combinations of mutant alleles in the same cell or organism. For example, combinations of different alleles of the same gene in a diploid can be used to determine whether a mutation is dominant or recessive or whether two different recessive mutations are in the same gene. Furthermore, combinations of mutations in different genes can be used to determine the order of gene function in a pathway or to identify functional relationships between genes such as suppression and synthetic enhancement. Generally speaking, all these methods can be viewed as analytical tests based on *gene function*. We will now consider a fundamentally different type of genetic analysis based on *gene position*. Studies designed to determine the position of a gene on a chromosome, often referred to as genetic mapping studies, can be used to identify the gene affected by a particular mutation or to determine whether two mutations are in the same gene.

In many organisms, genetic mapping studies rely on exchanges of genetic information that occur during meiosis. As shown in Figure 5-10a, genetic **recombination** takes place before the first meiotic cell division in germ cells, when the replicated chromosomes of each homologous pair align with each other. At this time, homologous DNA sequences on maternally and paternally derived chromatids can exchange with each other, a process known as crossing over. We now know that the resulting crossovers between homologous chromosomes provide structural links that are important for the proper segregation of pairs of homologous chromatids to opposite poles during the first meiotic cell division (for discussion see Chapter 19).

Consider two different mutations, one inherited from each parent, that are located close to each other on the same chromosome. Two different types of gametes can be produced according to whether a crossover occurs between the

FIGURE 5-10 Recombination during meiosis can be used to map the position of genes. (a) Shown is an individual that carries two mutations, designated *m1* (yellow) and *m2* (green), that are on the maternal and paternal versions of the same chromosome. If crossing over occurs at an interval between *m1* and *m2* before the first meiotic division, then two recombinant gametes are produced; one carries both *m1* and *m2*, whereas the other carries neither mutation. The longer the distance between two mutations on a chromatid, the more

mutations during meiosis. If no crossover occurs between them, gametes known as *parental types*, which contain either one or the other mutation, will be produced. In contrast, if a crossover occurs between the two mutations, gametes known as *recombinant types* will be produced. In this example, recombinant chromosomes would contain either both mutations or neither of them. The sites of recombination occur more or less at random along the length of chromosomes; thus the closer together two genes are, the less likely that recombination will occur between them during meiosis. In other words, *the less frequently recombination occurs between two genes on the same chromosome, the closer together they are*. Two genes that are on the same chromosome and that are sufficiently close together such that there are significantly fewer recombinant gametes produced than parental gametes are considered to be *genetically linked*.

The technique of recombinational mapping was devised in 1911 by A. Sturtevant while he was an undergraduate working in the laboratory of T. H. Morgan at Columbia University. Originally used in studies on *Drosophila*, this technique is still used today to assess the distance between two genetic loci on the same chromosome in many experimental organisms. A typical experiment designed to determine the map distance between two genetic positions would involve two

(b) Consider two linked genes *A* and *B* with recessive alleles *a* and *b*.

Cross of two mutants to construct a doubly heterozygous strain:

Cross of double heterozygote to test strain:

Genetic distance between *A* and *B* can be determined from frequency of parental and recombinant gametes:

$$\text{Genetic distance in cM} = 100 \times \frac{\text{recombinant gametes}}{\text{total gametes}}$$

likely they are to be separated by recombination and the greater the proportion of recombinant gametes produced. (b) In a typical mapping experiment, a strain that is heterozygous for two different genes is constructed. The frequency of parental or recombinant gametes produced by this strain can be determined from the phenotypes of the progeny in a testcross to a homozygous recessive strain. The genetic map distance in centimorgans (cM) is given as the percent of the gametes that are recombinant.

steps. In the first step, a strain is constructed that carries a different mutation at each position, or locus. In the second step, the progeny of this strain are assessed to determine the relative frequency of inheritance of parental or recombinant types. A typical way to determine the frequency of recombination between two genes is to cross one diploid parent heterozygous at each of the genetic loci to another parent homozygous for each gene. For such a cross, the proportion of recombinant progeny is readily determined because recombinant phenotypes will differ from the parental phenotypes. By convention, one *genetic map unit* is defined as the distance between two positions along a chromosome that results in one recombinant individual in 100 total progeny. The distance corresponding to this 1 percent recombination frequency is called a *centimorgan* (cM) in honor of Sturtevant's mentor, Morgan (Figure 5-10b).

A complete discussion of the methods of genetic mapping experiments is beyond the scope of this introductory discussion; however, two features of measuring distances by recombination mapping need particular emphasis. First, the frequency of genetic exchange between two loci is strictly proportional to the physical distance in base pairs separating them only for loci that are relatively close together (say, less than about 10 cM). For linked loci that are farther apart than

this, a distance measured by the frequency of genetic exchange tends to underestimate the physical distance because of the possibility of two or more crossovers occurring within an interval. In the limiting case in which the number of recombinant types will equal the number of parental types, the two loci under consideration could be far apart on the same chromosome or they could be on different chromosomes, and in such cases the loci are considered to be *unlinked*.

A second important concept needed for interpretation of genetic mapping experiments in different types of organisms is that although genetic distance is defined in the same way for different organisms, the relationship between recombination frequency (i.e., genetic map distance) and physical distance varies between organisms. For example, a 1 percent recombination frequency (i.e., a genetic distance of 1 cM) represents a physical distance of about 2.8 kilobases in yeast compared with a distance of about 400 kilobases in *Drosophila* and about 780 kilobases in humans.

One of the chief uses of genetic mapping studies is to locate the gene that is affected by a mutation of interest. The presence of many different already mapped genetic traits, or genetic markers, distributed along the length of a chromosome permits the position of an unmapped mutation to be determined by assessing its segregation with respect to these marker genes during meiosis. Thus the more markers that are available, the more precisely a mutation can be mapped. In Section 5.4, we will see how the genes affected in inherited human diseases can be identified using such methods. A second general use of mapping experiments is to determine whether two different mutations are in the same gene. If two mutations are in the same gene, they will exhibit tight linkage in mapping experiments, but if they are in different genes, they will usually be unlinked or exhibit weak linkage.

KEY CONCEPTS of Section 5.1

Genetic Analysis of Mutations to Identify and Study Genes

- Diploid organisms carry two copies (alleles) of each gene, whereas haploid organisms carry only one copy.
- Recessive mutations lead to a loss of function, which is masked if a normal allele of the gene is present. For the mutant phenotype to occur, both alleles must carry the mutation.
- Dominant mutations lead to a mutant phenotype in the presence of a normal allele of the gene. The phenotypes associated with dominant mutations often represent a gain of function but in the case of some genes result from a loss of function.
- In meiosis, a diploid cell undergoes one DNA replication and two cell divisions, yielding four haploid cells in which maternal and paternal chromosomes and their associated alleles are randomly assorted (see Figure 5-3).

- Dominant and recessive mutations exhibit characteristic segregation patterns in genetic crosses (see Figure 5-4).
- In haploid yeast, temperature-sensitive mutations are particularly useful for identifying and studying genes essential to survival.
- The number of functionally related genes involved in a process can be defined by complementation analysis (see Figure 5-7).
- The order in which genes function in a signaling pathway can be deduced from the phenotype of double mutants defective in two steps in the affected process.
- Functionally significant interactions between proteins can be deduced from the phenotypic effects of allele-specific suppressor mutations or synthetic lethal mutations.
- Genetic mapping experiments make use of crossing over between homologous chromosomes during meiosis to measure the genetic distance between two different mutations on the same chromosome.

5.2 DNA Cloning and Characterization

Detailed studies of the structure and function of a gene at the molecular level require large quantities of the individual gene in pure form. A variety of techniques, often referred to as *recombinant DNA technology*, are used in **DNA cloning**, which permits researchers to prepare large numbers of identical DNA molecules. **Recombinant DNA** is simply any DNA molecule composed of sequences derived from different sources.

The key to cloning a DNA fragment of interest is to link it to a **vector** DNA molecule that can replicate within a host cell. After a single recombinant DNA molecule, composed of a vector plus an inserted DNA fragment, is introduced into a host cell, the inserted DNA is replicated along with the vector, generating a large number of identical DNA molecules. The basic scheme can be summarized as follows:

Although investigators have devised numerous experimental variations, this flow diagram indicates the essential steps in DNA cloning. In this section, we first describe methods for isolating a specific sequence of DNA from a sea of other DNA sequences. This process often involves cutting the genome into

fragments and then placing each fragment in a vector so that the entire collection can be propagated as recombinant molecules in separate host cells. While many different types of vectors exist, our discussion will mainly focus on plasmid vectors in *E. coli* host cells, which are commonly used. Various techniques can then be employed to identify the sequence of interest from this collection of DNA fragments, known as a DNA library. Once a specific DNA fragment is isolated, it is typically characterized by determining the exact sequence of nucleotides in the molecule. We end with a discussion of the polymerase chain reaction (PCR). This powerful and versatile technique can be used in many ways to generate large quantities of a specific sequence and otherwise manipulate DNA in the laboratory. The various uses of cloned DNA fragments are discussed in subsequent sections.

Restriction Enzymes and DNA Ligases Allow Insertion of DNA Fragments into Cloning Vectors

A major objective of DNA cloning is to obtain discrete, small regions of an organism's DNA that constitute specific genes. In addition, only relatively small DNA molecules can be cloned in any of the available vectors. For these reasons, the very long DNA molecules that compose an organism's genome must be cleaved into fragments that can be inserted into the vector DNA. Two types of enzymes—**restriction enzymes** and **DNA ligases**—facilitate production of such recombinant DNA molecules.

Cutting DNA Molecules into Small Fragments Restriction enzymes are endonucleases produced by bacteria that typically recognize specific 4- to 8-bp sequences, called *restriction sites*, and then cleave both DNA strands at this site. Restriction sites commonly are short *palindromic* sequences; that is, the restriction-site sequence is the same on each DNA strand when read in the 5' to 3' direction (Figure 5-11).

FIGURE 5-11 Cleavage of DNA by the restriction enzyme EcoRI. This restriction enzyme from *E. coli* makes staggered cuts at the specific 6-bp palindromic sequence shown, yielding fragments with single-stranded, complementary “sticky” ends. Many other restriction enzymes also produce fragments with sticky ends.

For each restriction enzyme, bacteria also produce a *modification enzyme*, which protects a host bacterium's own DNA from cleavage by modifying the host DNA at or near each potential cleavage site. The modification enzyme adds a methyl group to one or two bases, usually within the restriction site. When a methyl group is present there, the restriction endonuclease is prevented from cutting the DNA. Together with the restriction endonuclease, the methylating enzyme forms a restriction-modification system that protects the host DNA while it destroys incoming foreign DNA (e.g., bacteriophage DNA or DNA taken up during transformation) by cleaving it at all the restriction sites in the DNA.

Many restriction enzymes make staggered cuts in the two DNA strands at their recognition site, generating fragments that have a single-stranded “tail” at both ends, *sticky ends* (see Figure 5-11). The tails on the fragments generated at a given restriction site are complementary to those on all other fragments generated by the same restriction enzyme. At room temperature, these single-stranded regions can transiently base-pair with those on other DNA fragments generated with the same restriction enzyme. A few restriction enzymes, such as *AluI* and *SmaI*, cleave both DNA strands at the same point within the restriction site, generating fragments with “blunt” (flush) ends in which all the nucleotides at the fragment ends are base-paired to nucleotides in the complementary strand.

The DNA isolated from an individual organism has a specific sequence, which purely by chance will contain a specific set of restriction sites. Thus a given restriction enzyme will cut the DNA from a particular source into a reproducible set of fragments called restriction fragments. The frequency with which a restriction enzyme cuts DNA, and thus the average size of the resulting restriction fragments, depends largely on the length of the recognition site. For example, a restriction enzyme that recognizes a 4-bp site will cleave DNA an average of once every 4⁴, or 256, base pairs, whereas an enzyme that recognizes an 8-bp sequence will cleave DNA an average of once every 4⁸ base pairs (~65 kbp). Restriction enzymes have been purified from several hundred different species of bacteria, allowing DNA molecules to be cut at a large number of different sequences corresponding to the recognition sites of these enzymes (Table 5-1).

Inserting DNA Fragments into Vectors DNA fragments with either sticky ends or blunt ends can be inserted into vector DNA with the aid of DNA ligases. During normal DNA replication, DNA ligase catalyzes the end-to-end joining (ligation) of short fragments of DNA called Okazaki fragments. For purposes of DNA cloning, purified DNA ligase is used to covalently join the ends of a restriction fragment and vector DNA that have complementary ends (Figure 5-12). The vector DNA and restriction fragment are covalently ligated together through the standard 3' to 5' phosphodiester bonds of DNA. In addition to ligating complementary sticky ends, the DNA ligase from bacteriophage T4 can ligate any two blunt DNA ends. However, blunt-end ligation is inherently inefficient and requires a higher concentration of both DNA and DNA ligase than does ligation of sticky ends.

TABLE 5-1 Selected Restriction Enzymes and Their Recognition Sequences

Enzyme	Source Microorganism	Recognition Site*	Ends Produced
<i>Bam</i> HI	<i>Bacillus amyloliquefaciens</i>	↓ -G-G-A-T-C-C- -C-C-T-A-G-G- ↑	Sticky
<i>Sau</i> 3A	<i>Staphylococcus aureus</i>	↓ -G-A-T-C- -C-T-A-G- ↑	Sticky
<i>Eco</i> RI	<i>Escherichia coli</i>	↓ -G-A-A-T-T-C- -C-T-T-A-A-G- ↑	Sticky
<i>Hind</i> III	<i>Haemophilus influenzae</i>	↓ -A-A-G-C-T-T- -T-T-C-G-A-A- ↑	Sticky
<i>Sma</i> I	<i>Serratia marcescens</i>	↓ -C-C-C-G-G-G- -G-G-G-C-C-C- ↑	Blunt
<i>Not</i> I	<i>Nocardia otitidis-caviarum</i>	↓ -G-C-G-G-C-C-G-C- -C-G-C-C-G-G-C-G- ↑	Sticky

*Many of these recognition sequences are included in a common polylinker sequence (see Figure 5-13).

***E. coli* Plasmid Vectors Are Suitable for Cloning Isolated DNA Fragments**

Plasmids are circular, double-stranded DNA (dsDNA) molecules that are separate from a cell's chromosomal DNA. These extrachromosomal DNAs, which occur naturally in bacteria and in lower eukaryotic cells (e.g., yeast), exist in a parasitic or symbiotic relationship with their host cell. Like the host-cell chromosomal DNA, plasmid DNA is duplicated before every cell division. During cell division, copies of the plasmid DNA segregate to each daughter cell, ensuring continued propagation of the plasmid through successive generations of the host cell.

The plasmids most commonly used in recombinant DNA technology are those that replicate in *E. coli*. Investigators have engineered these plasmids to optimize their use as vectors in DNA cloning. For instance, removal of unneeded portions from naturally occurring *E. coli* plasmids yields plasmid vectors ~1.2–3 kb in circumferential length that contain three regions essential for DNA cloning: a replication origin; a marker that permits selection, usually a drug-resistance gene; and a region in which exogenous DNA fragments can be

inserted (Figure 5-13). Host-cell enzymes replicate a plasmid beginning at the replication origin (ORI), a specific DNA sequence of 50–100 base pairs. Once DNA replication is initiated at the ORI, it continues around the circular plasmid regardless of its nucleotide sequence. Thus any DNA sequence inserted into such a plasmid is replicated along with the rest of the plasmid DNA.

Figure 5-14 outlines the general procedure for cloning a DNA fragment using *E. coli* plasmid vectors. When *E. coli* cells are mixed with recombinant vector DNA under certain conditions, a small fraction of the cells will take up the plasmid DNA, a process known as **transformation**. Typically, 1 cell in about 10,000 incorporates a *single* plasmid DNA molecule and thus becomes transformed. After plasmid vectors are incubated with *E. coli*, those cells that take up the plasmid can be easily selected from the much larger number of cells. For instance, if the plasmid carries a gene that confers resistance to the antibiotic ampicillin, transformed cells can be selected by growing them in an ampicillin-containing medium.

DNA fragments from a few base pairs up to ~10 kb can be inserted into plasmid vectors. When a recombinant plasmid

FIGURE 5-12 Ligation of restriction fragments with complementary sticky ends. In this example, vector DNA cut with *EcoRI* is mixed with a sample containing restriction fragments produced by cleaving genomic DNA with several different restriction enzymes. The short base sequences composing the sticky ends of each fragment type are shown. The sticky end on the cut vector DNA (a') base-pairs only with the complementary sticky ends on the *EcoRI* fragment (a) in the genomic sample. The adjacent 3' hydroxyl and 5' phosphate groups (red) on the base-paired fragments then are covalently joined (ligated) by T4 DNA ligase.

with an inserted DNA fragment transforms an *E. coli* cell, all the antibiotic-resistant progeny cells that arise from the initial transformed cell will contain plasmids with the same inserted DNA. The inserted DNA is replicated along with the rest of the plasmid DNA and segregates to daughter cells as

the colony grows. In this way, the initial fragment of DNA is replicated in the colony of cells into a large number of identical copies. Since all the cells in a colony arise from a single transformed parental cell, they constitute a clone of cells, and the initial fragment of DNA inserted into the parental plasmid is referred to as *cloned DNA* or a *DNA clone*.

The versatility of an *E. coli* plasmid vector is increased by the addition of a *polylinker*, a synthetically generated sequence containing one copy of several different restriction sites that are not present elsewhere in the plasmid sequence (see Figure 5-13). When such a vector is treated with a restriction enzyme that recognizes a restriction site in the polylinker, the vector is cut only once within the polylinker. Subsequently, any DNA fragment of appropriate length produced with the same restriction enzyme can be inserted into the cut plasmid with DNA ligase. Plasmids containing a polylinker permit a researcher to use the same plasmid vector when cloning DNA fragments generated with different restriction enzymes, which simplifies experimental procedures.

For some purposes, such as the isolation and manipulation of large segments of the human genome, it is desirable to clone DNA segments as large as several megabases [1 megabase (Mb) = 1 million nucleotides]. For this purpose specialized plasmid vectors known as BACs (*bacterial artificial chromosomes*) have been developed. One type of BAC uses a replication origin derived from an endogenous plasmid of *E. coli* known as the *F factor*. The *F factor* and cloning vectors derived from it can be stably maintained at a single copy per *E. coli* cell even when they contain inserted sequences of up to about 2 Mb. Production of BAC libraries requires special methods for the isolation, ligation, and transformation of large segments of DNA because segments of DNA larger than about 20 kb are highly vulnerable to mechanical breakage by even standard manipulations such as pipetting.

cDNA Libraries Represent the Sequences of Protein-Coding Genes

A collection of DNA molecules each cloned into a vector molecule is known as a **DNA library**. When genomic DNA from a particular organism is the source of the starting DNA, the set of clones that collectively represent all the DNA sequences in the genome is known as a *genomic library*. Such genomic

FIGURE 5-13 Basic components of a plasmid cloning vector that can replicate within an *E. coli* cell. Plasmid vectors contain a selectable gene such as *amp^r*, which encodes the enzyme β -lactamase and confers resistance to ampicillin. Exogenous DNA can be inserted into the bracketed region without disturbing the ability of the plasmid to replicate or express the *amp^r* gene. Plasmid vectors also contain a replication origin (ORI) sequence where DNA replication is initiated by host-cell enzymes. Inclusion of a synthetic polylinker containing the recognition sequences for several different restriction enzymes increases the versatility of a plasmid vector. The vector is designed so that each site in the polylinker is unique on the plasmid.

EXPERIMENTAL FIGURE 5-14 DNA cloning in a plasmid vector permits amplification of a DNA fragment. A fragment of DNA to be cloned is first inserted into a plasmid vector containing an ampicillin-resistance gene (*amp^r*), such as that shown in Figure 5-13. Only the few cells transformed by incorporation of a plasmid molecule will survive on ampicillin-containing medium. In transformed cells, the plasmid DNA replicates and segregates into daughter cells, resulting in formation of an ampicillin-resistant colony.

libraries are ideal for representing the genetic content of relatively simple organisms such as bacteria or yeast but present certain experimental difficulties for higher eukaryotes. First, the genes from such organisms usually contain extensive intron sequences and therefore can be too large to be inserted intact into plasmid vectors. As a result, the sequences of individual genes are broken apart and carried in more than one clone. Moreover, the presence of introns and long intergenic regions in genomic DNA often makes it difficult to identify the important parts of a gene that actually encode protein sequences. For example, only about 1.5 percent of the human genome actually represents protein-coding gene sequences. Thus for many studies, cellular mRNAs, which lack the noncoding regions present in genomic DNA, are a more useful starting material for generating a DNA library. In this approach, DNA copies of mRNAs, called **complementary DNAs (cDNAs)**, are synthesized and cloned into plasmid vectors. A large collection of the resulting cDNA clones, representing all the mRNAs expressed in a cell type, is called a *cDNA library*.

cDNAs Prepared by Reverse Transcription of Cellular mRNAs Can Be Cloned to Generate cDNA Libraries

The first step in preparing a cDNA library is to isolate the total mRNA from the cell type or tissue of interest. Because of their poly(A) tails, mRNAs are easily separated from the much more prevalent rRNAs and tRNAs present in a cell extract by use of a column to which short strings of thymidylate (oligo-dTs) are linked to the matrix. The general procedure for preparing a cDNA library from a mixture of cellular mRNAs is outlined in Figure 5-15. The enzyme reverse transcriptase, which is found in retroviruses, is used to synthesize a strand of DNA complementary to each mRNA molecule, starting from an oligo-dT primer (steps 1 and 2). The resulting cDNA-mRNA hybrid molecules are converted in several steps to double-stranded cDNA molecules corresponding to all the mRNA molecules in the original preparation (steps 3–5). Each double-stranded cDNA contains an oligo-dC-oligo-dG double-stranded region at one end and an oligo-dT-oligo-dA double-stranded region at the other end. Methylation of the cDNA protects it from subsequent restriction enzyme cleavage (step 6).

To prepare double-stranded cDNAs for cloning, short double-stranded DNA molecules containing the recognition site for a particular restriction enzyme are ligated to both ends of the cDNAs using DNA ligase from bacteriophage T4 (Figure 5-15, step 7). As noted earlier, this ligase can join “blunt-ended” double-stranded DNA molecules lacking sticky ends. The resulting molecules are then treated with the restriction enzyme specific for the attached linker, generating

FIGURE 5-15 A cDNA library contains representative copies of cellular mRNA sequences. A mixture of mRNAs is the starting point for preparing recombinant plasmid clones each containing a cDNA. Transforming *E. coli* with the recombinant plasmids generates a set of cDNA clones representing all the cellular mRNAs. See the text for a step-by-step discussion.

cDNA molecules with sticky ends (step **8a**). In a separate procedure, plasmid DNA is treated with the same restriction enzyme to produce the appropriate sticky ends (step **8b**).

The vector and the collection of cDNAs, all containing complementary sticky ends, then are mixed and joined covalently by DNA ligase (Figure 5-15, step **9**). The resulting DNA molecules are transformed into *E. coli* cells to generate individual clones; each clone carrying a cDNA derived from a single mRNA.

Because different genes are transcribed at very different rates, cDNA clones corresponding to abundantly transcribed genes will be represented many times in a cDNA library, whereas cDNAs corresponding to infrequently transcribed genes will be extremely rare or not present at all. This property is advantageous if an investigator is interested in a gene that is transcribed at a high rate in a particular cell type. In this case, a cDNA library prepared from mRNAs expressed in that cell type will be enriched in the cDNA of interest, facilitating isolation of clones carrying that cDNA from the library. However, to have a reasonable chance of including clones corresponding to slowly transcribed genes, mammalian cDNA libraries must contain 10^6 – 10^7 individual recombinant clones.

DNA Libraries Can Be Screened by Hybridization to an Oligonucleotide Probe

Both genomic and cDNA libraries of various organisms contain hundreds of thousands to upward of a million individual clones in the case of higher eukaryotes. Two general approaches are available for screening libraries to identify clones carrying a gene or other DNA region of interest: (1) detection with oligonucleotide probes that bind to the clone of interest and (2) detection based on expression of the encoded protein. Here we describe the first method; an example of the second method is presented in the next section.

The basis for screening with oligonucleotide probes is **hybridization**, the ability of complementary single-stranded DNA or RNA molecules to associate (hybridize) specifically with each other via base pairing. As discussed in Chapter 4, double-stranded (duplex) DNA can be denatured (melted) into single strands by heating in a dilute salt solution. If the temperature then is lowered and the ion concentration raised, complementary single strands will reassociate (hybridize) into duplexes. In a mixture of nucleic acids, only complementary single strands (or strands containing complementary regions) will reassociate; moreover, the extent of their reassociation is virtually unaffected by the presence of noncomplementary strands. As we will see later in this chapter, the ability to identify a particular DNA or RNA sequence within a highly complex mixture of molecules through nucleic acid hybridization is the basis for many techniques employed to study gene expression.

The steps involved in screening an *E. coli* plasmid cDNA library are depicted in Figure 5-16. First, the DNA to be screened

must be attached to a solid support. A *replica* of the petri dish containing a large number of individual *E. coli* clones is reproduced on the surface of a nitrocellulose membrane. The DNA on the membrane is denatured, and the membrane is then incubated in a solution containing a probe specific for the recombinant DNA containing the fragment of interest that is labeled either radioactively or fluorescently. Under hybridization conditions (near neutral pH, 40–65 °C, 0.3–0.6 M NaCl), this labeled probe hybridizes to any complementary nucleic acid strands bound to the membrane. Any excess probe that does not hybridize is washed away, and the labeled hybrids are detected by autoradiography or by fluorescent imaging of the filter. This technique can be used to screen both genomic and cDNA libraries but is most commonly used to isolate specific cDNAs.

Clearly, identification of specific clones by the membrane-hybridization technique depends on the availability of complementary radiolabeled probes. For an oligonucleotide to be useful as a probe, it must be long enough for its sequence to occur uniquely in the clone of interest and not in any other clones. For most purposes, this condition is satisfied by oligonucleotides containing about 20 nucleotides. This is because a specific 20-nucleotide sequence occurs once in every 4^{20} ($\sim 10^{12}$) nucleotides. Since all genomes are much smaller ($\sim 3 \times 10^9$ nucleotides for humans), a specific 20-nucleotide sequence in a genome usually occurs only once. With automated instruments now available, researchers can program the chemical synthesis of oligonucleotides of specific sequence up to about 100 nucleotides long. Longer probes can be prepared by the polymerase chain reaction (PCR), a widely used technique for amplifying specific DNA sequences that is described later in this chapter.

How might an investigator design an oligonucleotide probe to identify a clone encoding a particular protein? It helps if all or a part of the amino acid sequence of the protein is known. Thanks to the availability of the complete genomic sequences for humans and many other organisms, including all of the model organisms such as the mouse, *Drosophila*, and the roundworm *Caenorhabditis elegans*, a researcher can use an appropriate computer program to search the genomic sequence database for the coding sequence that corresponds to the amino acid sequence of the protein under study. If a match is found, then a single, unique DNA probe based on this known genomic sequence will hybridize perfectly with the clone encoding the protein of interest.

Yeast Genomic Libraries Can Be Constructed with Shuttle Vectors and Screened by Functional Complementation

In some cases, a DNA library can be screened for the ability to express a functional protein that complements a **recessive** mutation. Such a screening strategy would be an efficient way to

EXPERIMENTAL FIGURE 5-16 cDNA libraries can be screened with a radiolabeled probe to identify a clone of interest. The appearance of a spot on the autoradiogram indicates the presence of a recombinant clone containing DNA complementary to the probe. The position of the spot on the autoradiogram is the mirror image of the position of that particular clone on the original petri dish

(although for ease of comparison, it is not shown reversed here). Aligning the autoradiogram with the original petri dish will locate the corresponding clone from which *E. coli* cells can be recovered. (b) This autoradiogram shows five colonies (arrows) of *E. coli* containing the desired cDNA. [Part (b) from H. Fromm and N.-H. Chua, 1992, *Plant. Mol. Biol. Rep.* 10:199.]

isolate a cloned gene that corresponds to an interesting recessive mutation identified in an experimental organism. To illustrate this method, referred to as **functional complementation**, we describe how yeast genes cloned in special *E. coli* plasmids can be introduced into mutant yeast cells to identify the wild-type gene that is defective in the mutant strain.

Libraries constructed for the purpose of screening among yeast gene sequences usually are constructed from genomic DNA rather than cDNA. Because *Saccharomyces* genes do not contain multiple introns, they are sufficiently compact that the entire sequence of a gene can be included in a genomic DNA fragment inserted into a plasmid vector. To

construct a plasmid genomic library that is to be screened by functional complementation in yeast cells, the plasmid vector must be capable of replication in both *E. coli* cells and yeast cells. This type of vector, capable of propagation in two different hosts, is called a shuttle vector. The structure of a typical yeast shuttle vector is shown in Figure 5-17a. This vector contains the basic elements that permit cloning of DNA fragments in *E. coli*. In addition, the shuttle vector contains an autonomously replicating sequence (ARS), which functions as an origin for DNA replication in yeast; a yeast centromere (called CEN), which allows faithful segregation of the plasmid during yeast cell division; and a yeast gene encoding an enzyme for uracil synthesis (*URA3*), which serves as a selectable marker in an appropriate yeast mutant.

To increase the probability that all regions of the yeast genome are successfully cloned and represented in the plasmid library, the genomic DNA usually is only partially digested to yield overlapping restriction fragments of ~10 kb. These fragments are then ligated into the shuttle vector in which the polylinker has been cleaved with a restriction enzyme that produces sticky ends complementary to those on the yeast DNA fragments (Figure 5-17b). Because the 10-kb restriction fragments of yeast DNA are incorporated into the shuttle vectors randomly, at least 10^5 *E. coli* colonies, each containing a particular recombinant shuttle vector, are necessary to ensure that each region of yeast DNA has a high probability of being represented in the library at least once.

Figure 5-18 outlines how such a yeast genomic library can be screened to isolate the wild-type gene corresponding to one of the temperature-sensitive *cdc* mutations mentioned earlier in this chapter. The starting yeast strain is a double mutant that requires uracil for growth due to a *ura3* mutation and is temperature sensitive due to a *cdc28* mutation identified by its phenotype (see Figure 5-6). Recombinant plasmids isolated from the yeast genomic library are mixed with yeast cells under conditions that promote transformation of the cells with foreign DNA. Since transformed yeast

cells carry a plasmid-borne copy of the wild-type *URA3* gene, they can be selected by their ability to grow in the absence of uracil. Typically, about 20 petri dishes, each containing about 500 yeast transformants, are sufficient to represent the entire yeast genome. This collection of yeast transformants can be maintained at 23 °C, a temperature permissive for growth of the *cdc28* mutant. The entire collection on 20 plates is then transferred to replica plates, which are placed at 36 °C, a nonpermissive temperature for *cdc* mutants. Yeast colonies that carry recombinant plasmids expressing a wild-type copy

EXPERIMENTAL FIGURE 5-17 A yeast genomic library can be constructed in a plasmid shuttle vector that can replicate in yeast and *E. coli*. (a) Components of a typical plasmid shuttle vector for cloning *Saccharomyces* genes. The presence of a yeast origin of DNA replication (ARS) and a yeast centromere (CEN) allows stable replication and segregation in yeast. Also included is a yeast selectable marker such as *URA3*, which allows a *ura3* mutant to grow on medium lacking uracil. Finally, the vector contains sequences for replication and selection in *E. coli* (ORI and *amp^r*) and a polylinker for easy insertion of yeast DNA fragments. (b) Typical protocol for constructing a yeast genomic library. Partial digestion of total yeast genomic DNA with *Sau3A* is adjusted to generate fragments with an average size of about 10 kb. The vector is prepared to accept the genomic fragments by digestion with *Bam*HI, which produces the same sticky ends as *Sau3A*. Each transformed clone of *E. coli* that grows after selection for ampicillin resistance contains a single type of yeast DNA fragment.

EXPERIMENTAL FIGURE 5-18 Screening of a yeast genomic library by functional complementation can identify clones carrying the normal form of a mutant yeast gene. In this example, a wild-type *CDC* gene is isolated by complementation of a *cdc* yeast mutant. The *Saccharomyces* strain used for screening the yeast library carries *ura3* and a temperature-sensitive *cdc* mutation. This mutant strain is grown and maintained at a permissive temperature (23 °C). Pooled recombinant plasmids prepared as shown in Figure 5-17 are incubated with the

mutant yeast cells under conditions that promote transformation. The relatively few transformed yeast cells, which contain recombinant plasmid DNA, can grow in the absence of uracil at 23 °C. When transformed yeast colonies are replica-plated and placed at 36 °C (a nonpermissive temperature), only clones carrying a library plasmid that contains the wild-type copy of the *CDC* gene will survive. LiOAC = lithium acetate; PEG = polyethylene glycol.

of the *CDC28* gene will be able to grow at 36 °C. Once temperature-resistant yeast colonies have been identified, plasmid DNA can be extracted from the cultured yeast cells and analyzed by subcloning and DNA sequencing, topics we take up next.

Gel Electrophoresis Allows Separation of Vector DNA from Cloned Fragments

In order to manipulate or sequence a cloned DNA fragment, it sometimes must first be separated from the vector DNA. This can be accomplished by cutting the recombinant DNA clone with the same restriction enzyme used to produce the recombinant vectors originally. The cloned DNA and vector DNA then are subjected to gel electrophoresis, a powerful method for separating DNA molecules of different size (Figure 5-19).

Near neutral pH, DNA molecules carry a large negative charge and therefore move toward the positive electrode during gel electrophoresis. Because the gel matrix restricts random diffusion of the molecules, molecules of the same length migrate together as a band whose width equals that of the well into which the original DNA mixture was placed at the start of the electrophoretic run. Smaller molecules move through the gel matrix more readily than larger molecules, so that molecules of different length migrate as distinct bands. Smaller DNA molecules from about 10 to 2000

nucleotides can be separated electrophoretically on *polyacrylamide gels*, and larger molecules from about 200 nucleotides to more than 20 kb on *agarose gels*.

A common method for visualizing separated DNA bands on a gel is to incubate the gel in a solution containing the fluorescent dye ethidium bromide. This planar molecule binds to DNA by intercalating between the base pairs. Binding concentrates ethidium in the DNA and also increases its intrinsic fluorescence. As a result, when the gel is illuminated with ultraviolet light, the regions of the gel containing DNA fluoresce much more brightly than the regions of the gel without DNA.

Once a cloned DNA fragment, especially a long one, has been separated from vector DNA, it often is treated with various restriction enzymes to yield smaller fragments. After separation by gel electrophoresis, all or some of these smaller fragments can be ligated individually into a plasmid vector and cloned in *E. coli* by the usual procedure. This process, known as *subcloning*, is an important step in rearranging parts of genes into useful new configurations. For instance, an investigator who wants to change the conditions under which a gene is expressed might use subcloning to replace the normal promoter associated with a cloned gene with a DNA segment containing a different promoter. Subcloning also can be used to obtain cloned DNA fragments that are of an appropriate length for determining the nucleotide sequence.

EXPERIMENTAL FIGURE 5-19 Gel electrophoresis separates DNA molecules of different lengths. (a) A gel is prepared by pouring a liquid containing either melted agarose or unpolymerized acrylamide between two glass plates a few millimeters apart. As the agarose solidifies or the acrylamide polymerizes into polyacrylamide, a gel matrix (orange ovals) forms consisting of long, tangled chains of polymers. The dimensions of the interconnecting channels, or pores, depend on the concentration of the agarose or acrylamide used to form the gel. The separated bands can be visualized by autoradiography (if the fragments are radiolabeled) or by addition of a fluorescent dye (e.g., ethidium bromide) that binds to DNA. (b) A photograph of a gel stained with ethidium bromide (EtBr). EtBr binds to DNA and fluoresces under UV light. The bands in the far left and far right lanes are known as DNA ladders—DNA fragments of known size that serve as a reference for determining the length of the DNA fragments in the experimental sample. [Part (b) Science Photo Library.]

The Polymerase Chain Reaction Amplifies a Specific DNA Sequence from a Complex Mixture

If the nucleotide sequences at the ends of a particular DNA region are known, the intervening fragment can be amplified directly by the **polymerase chain reaction (PCR)**. Here we describe the basic PCR technique and three situations in which it is used.

The PCR depends on the ability to alternately denature (melt) double-stranded DNA molecules and hybridize complementary single strands in a controlled fashion. As outlined in Figure 5-20, a typical PCR procedure begins by heat-denaturation at 95 °C of a DNA sample into single strands. Next, two synthetic oligonucleotides complementary to the 3' ends of the target DNA segment of interest are added in great excess to the denatured DNA, and the temperature is lowered to 50–60 °C. These specific oligonucleotides, which are at a very high concentration, will hybridize with their complementary sequences in the DNA sample, whereas the long strands of the sample DNA remain apart because of their low concentration. The hybridized oligonucleotides then serve as primers for DNA chain synthesis in the presence of deoxynucleotides (dNTPs) and a temperature-resistant DNA polymerase such as that from *Thermus aquaticus* (a bacterium that lives in hot springs). This enzyme, called *Taq polymerase*, can remain active even after being heated to 95 °C and can extend the primers at temperatures up to 72 °C. When synthesis is complete, the whole mixture

FIGURE 5-20 The polymerase chain reaction (PCR) is widely used to amplify DNA regions of known sequences. To amplify a specific region of DNA, an investigator will chemically synthesize two different oligonucleotide primers complementary to sequences of approximately 18 bases flanking the region of interest (designated as light blue and dark blue bars). The complete reaction is composed of a complex mixture of double-stranded DNA (usually genomic DNA containing the target sequence of interest), a stoichiometric excess of both primers, the four deoxynucleoside triphosphates, and a heat-stable DNA polymerase known as *Taq* polymerase. During each PCR cycle, the reaction mixture is first heated to separate the strands and then cooled to allow the primers to bind to complementary sequences flanking the region to be amplified. *Taq* polymerase then extends each primer from its 3' end, generating newly synthesized strands that extend in the 3' direction to the 5' end of the template strand. During the third cycle, two double-stranded DNA molecules are generated equal in length to the sequence of the region to be amplified. In each successive cycle the target segment, which will anneal to the primers, is duplicated and will eventually vastly outnumber all other DNA segments in the reaction mixture. Successive PCR cycles can be automated by cycling the reaction for timed intervals at high temperature for DNA melting and at a defined lower temperature for the annealing and elongation parts of the cycle. A reaction that cycles 20 times will amplify the specific target sequence 1-million-fold.

is then heated to 95 °C to denature the newly formed DNA duplexes. After the temperature is lowered again, another cycle of synthesis takes place because excess primer is still present. Repeated cycles of denaturation (heating) followed by hybridization and synthesis (cooling) quickly amplify the sequence of interest. At each cycle, the number of copies of the sequence between the primer sites is doubled; therefore, the desired sequence increases exponentially—about a million-fold after 20 cycles—whereas all other sequences in the original DNA sample remain unamplified.

Direct Isolation of a Specific Segment of Genomic DNA For organisms in which all or most of the genome has been sequenced, PCR amplification starting with the total genomic DNA often is the easiest way to obtain a specific DNA region of interest for cloning. In this application, the two oligonucleotide primers are designed to hybridize to sequences flanking the genomic region of interest and to include sequences that are recognized by specific restriction enzymes (Figure 5-21). After amplification of the desired target sequence for about 20 PCR cycles, cleavage with the appropriate restriction enzymes produces sticky ends that allow efficient ligation of the fragment into a plasmid vector cleaved by the same restriction enzymes in the polylinker. The resulting recombinant plasmids, all carrying the identical genomic DNA segment, can then be cloned in *E. coli* cells. With certain refinements of the PCR, even DNA segments greater than 10 kb in length can be amplified and cloned in this way.

Note that this method does not involve cloning of large numbers of restriction fragments derived from genomic DNA and their subsequent screening to identify the specific fragment of interest. In effect, the PCR method inverts this traditional approach and so avoids its most tedious aspects. The PCR method is useful for isolating gene sequences to be manipulated in a variety of useful ways described later. In

EXPERIMENTAL FIGURE 5-21 A specific target region in total genomic DNA can be amplified by PCR for use in cloning. Each primer for PCR is complementary to one end of the target sequence and includes the recognition sequence for a restriction enzyme that does not have a site within the target region. In this example, primer 1 contains a *Bam*HI sequence, whereas primer 2 contains a *Hind*III sequence. (Note that for clarity, in any round amplification of only one of the two strands is shown, the one in brackets.) After amplification, the target segments are treated with appropriate restriction enzymes, generating fragments with sticky ends. These can be incorporated into complementary plasmid vectors and cloned in *E. coli* by the usual procedure (see Figure 5-13).

To carry out a quantitative RT-PCR reaction, the amount of double-stranded DNA sequence produced by each amplification cycle is determined as the amplification of a particular mRNA sequence proceeds. By extrapolation from these amounts, an estimate of the amount of starting mRNA sequence can be obtained. Such quantitative RT-PCR carried out on tissues or whole organisms using primers targeted to genes of interest provide one of the most accurate means to follow changes in gene expression.

Preparation of Probes Earlier we mentioned that oligonucleotide probes for hybridization assays can be chemically synthesized. Preparation of such probes by PCR amplification requires chemical synthesis of only two relatively short primers corresponding to the two ends of the target sequence. The starting sample for PCR amplification of the target sequence can be a preparation of genomic DNA or a preparation of cDNA synthesized from the total cellular mRNA. To generate a radiolabeled product from PCR, ^{32}P -labeled dNTPs are included during the last several amplification cycles or a fluorescently labeled product can be obtained by using fluorescently labeled dNTPs during the last amplification cycles. Because probes prepared by PCR are relatively long and have many radioactive or fluorescent nucleotides incorporated into them, these probes usually give a stronger and more specific signal than chemically synthesized probes.

Tagging of Genes by Insertion Mutations Another useful application of the PCR is to amplify a “tagged” gene from the genomic DNA of a mutant strain. This approach is a simpler method for identifying genes associated with a particular mutant phenotype than screening of a library by functional complementation (see Figure 5-18).

The key to this use of the PCR is the ability to produce mutations by insertion of a known DNA sequence into the genome of an experimental organism. Such insertion mutations can be generated by use of mobile DNA elements, which can move (or transpose) from one chromosomal site to another. As discussed in more detail in Chapter 6, these DNA sequences occur naturally in the genomes of most organisms and may give rise to loss-of-function mutations if they transpose into a protein-coding region.

addition, the PCR method can be used to isolate gene sequences from mutant organisms to determine how they differ from the wild type.

A variation on the PCR method allows PCR amplification of a specific cDNA sequence from cellular mRNAs. This method, known as *reverse transcriptase-PCR* (RT-PCR), begins with the same procedure described previously for isolation of cDNA from a collection of cellular mRNAs. Typically, an oligo-dT primer, which will hybridize to the 3' poly(A) tail of the mRNA, is used as the primer for the first strand of cDNA synthesis by reverse transcriptase. A specific cDNA can then be isolated from this complex mixture of cDNAs by PCR amplification using two oligonucleotide primers designed to match sequences at the 5' and 3' ends of the corresponding mRNA. As described previously, these primers could be designed to include restriction sites to facilitate the insertion of amplified cDNA into a suitable plasmid vector.

RT-PCR can be performed so that the starting amount of a particular cellular mRNA can be determined accurately.

FIGURE 5-22 The genomic sequence at the insertion site of a transposon is revealed by PCR amplification and sequencing. To obtain the DNA sequence of the insertion site of a P-element transposon it is necessary to PCR-amplify the junction between known transposon sequences and unknown flanking chromosomal sequences. One method to achieve this is to cleave genomic DNA with a restriction enzyme that cleaves once within the transposon sequence. Ligation of the resulting restriction fragments will generate circular DNA molecules. By using appropriately designed DNA primers that match transposon sequences, it is possible to PCR-amplify the desired junction fragment. Finally, a DNA sequencing reaction (see Figures 5-23 and 5-24) is performed using the PCR-amplified fragment as a template and an oligonucleotide primer that matches sequences near the end of the transposon to obtain the sequence of the junction between the transposon and chromosome.

For example, researchers have modified a *Drosophila* mobile DNA element, known as the *P element*, to optimize its use in the experimental generation of insertion mutations. Once it has been demonstrated that insertion of a *P element* causes a mutation with an interesting phenotype, the genomic sequences adjacent to the insertion site can be amplified by a variation of the standard PCR protocol that uses synthetic primers complementary to the known *P-element* sequence but that allows unknown neighboring sequences to be amplified. One such method, depicted in Figure 5-22, begins by cleaving *Drosophila* genomic DNA containing a *P-element* insertion with a restriction enzyme that cleaves once within the *P-element* DNA. The collection of cleaved DNA fragments treated with DNA ligase yields circular molecules, some of which will contain *P-element* DNA. The chromosomal region flanking the *P element* can then be amplified by PCR using primers that match *P-element* sequences and are elongated in opposite directions. The sequence of the resulting amplified fragment can then be determined using a third DNA primer. The crucial sequence for identifying the site of *P-element* insertion is the junction between the end of the *P-element* and genomic sequences. Overall, this approach avoids the cloning of large numbers of DNA fragments and their screening to detect a cloned DNA corresponding to a mutated gene of interest.

Similar methods have been applied to other organisms for which insertion mutations can be generated using either

mobile DNA elements or viruses with sequenced genomes that can insert randomly into the genome.

Cloned DNA Molecules Are Sequenced Rapidly by Methods Based on PCR

The complete characterization of any cloned DNA fragment requires determination of its nucleotide sequence. The technology used to determine the sequence of a DNA segment represents one of the most rapidly developing fields in molecular biology. In the 1970s, F. Sanger and his colleagues developed the chain-termination procedure, which served as the basis for most DNA sequencing methods for the next 30 years. The idea behind this method is to synthesize from the DNA fragment to be sequenced a set of daughter strands that are labeled at one end and terminate at one of the four nucleotides. Separation of the truncated daughter strands by gel electrophoresis, which can resolve strands that differ in length by one nucleotide, can then reveal the length of all strands ending in G, A, T, or C. From these collections of strands of different lengths, the nucleotide sequence of the original DNA fragment can be established. The Sanger method has undergone many refinements and now can be fully automated, but because each new DNA sequence requires a separate individual sequencing reaction, the overall rate by which new DNA sequences can be produced by this method is limited by the total number of reactions that can be performed at one time.

EXPERIMENTAL FIGURE 5-23 Generation of clusters of identical DNA molecules attached to a solid support. A large collection of DNA molecules to be sequenced is ligated to double-stranded linkers, which become attached to each end of the fragment. The DNA is then amplified by PCR using primers matching the sequences of the linkers that are covalently attached to a solid substrate. Ten cycles of amplification yield about 1000 identical copies of the DNA fragment localized in a small cluster, which is attached at both ends to the solid substrate. These reactions are optimized to produce as many as 3×10^9 discrete, non-overlapping clusters that are ready to be sequenced.

A breakthrough in sequencing technology occurred when methods were devised to allow a single sequencing instrument to carry out billions of sequencing reactions simultaneously by localizing them in tiny clusters on the surface of a solid substrate. Since 2007, when the so-called *next generation* sequencers became commercially available, the capacity for new sequence production increased enormously and since then has been doubling every year. In one popular sequencing method, billions of different DNA strands to be sequenced are prepared by ligating double-stranded linkers to their ends (Figure 5-23). Next the DNA fragments are amplified by PCR using primers that match the linker sequences. This PCR amplification reaction

EXPERIMENTAL FIGURE 5-24 Using fluorescently tagged deoxyribonucleotide triphosphates for sequence determination. The reaction begins by cleaving one strand of the clustered DNA. After melting, a single DNA strand remains attached to the flow cell. A synthetic oligodeoxynucleotide is used as the primer for the polymerization reaction that contains dNTPs, each fluorescently tagged with a different color. The fluorescent tag is designed to block the 3' OH group on the dNTP so that once the fluorescent dNTP has been incorporated, further elongation is not possible. Because DNA polymerase will incorporate the same fluorescent dNTP into each of the ~ 1000 DNA copies in a cluster, the entire cluster will be uniformly labeled with the same fluorescent color, which can be imaged in a special microscope. Once all of the clusters have been imaged, the fluorescent tags are removed by a chemical reaction that leaves a new primer terminus available for the next cycle of fluorescently labeled dNTP addition. A typical sequencing reaction may carry out 100 polymerization cycles, allowing 100 bases of sequence for each cluster to be determined. Thus a total sequencing reaction of this type may generate as much as 3×10^{11} bases of sequence information in about two days. [OpenWetWare user Andrea Loehr (http://openwetware.org/wiki/User:Andrea_Loehr).]

differs from the standard PCR amplification shown in Figure 5-20 in that the primers used are covalently attached to a solid substrate. Thus as the PCR amplification proceeds, one end of each daughter DNA strand is covalently linked to the substrate and at the end of the amplification ~1,000 identical PCR products are linked to the surface in a tight cluster.

These clusters can then be sequenced by using a special microscope to image fluorescently labeled deoxyribonucleotides (dNTPs) as they are incorporated by DNA polymerase one at a time into a growing DNA chain (Figure 5-24). First, one strand is cut and washed out, leaving a single-stranded DNA template. Then sequencing is carried out on the ~1,000 identical templates in clusters, one nucleotide at a time. All four dNTPs are fluorescently labeled and added to the sequencing reaction. After they are allowed to anneal, the substrate is imaged and the color of each cluster is recorded. Next the fluorescent tag is chemically removed and a new dNTP is allowed to bind. This cycle is repeated about 100 times, resulting in billions of ~100 nucleotide sequences.

In order to sequence a long continuous region of genomic DNA or even the entire genome of an organism, researchers usually employ one of the strategies outlined in Figure 5-25. The first method requires the isolation of a collection of cloned DNA fragments whose sequences overlap. Once the sequence of one of these fragments is determined, oligonucleotides based on that sequence can be chemically synthesized for use as primers in sequencing the adjacent overlapping fragments. In this way, the sequence of a long stretch of DNA is determined incrementally by sequencing of the overlapping cloned DNA fragments that compose it. A second method, which is called *whole genome shotgun sequencing*, bypasses the time-consuming step of isolating an ordered collection of DNA segments that span the genome. This method involves simply sequencing random clones from a genomic library. A total number of clones are chosen for sequencing so that on average each segment of the genome is sequenced about 10 times. This degree of coverage ensures that each segment of the genome is sequenced more than once. The entire genomic sequence is then assembled using a computer algorithm that aligns all the sequences, using their regions of overlap. Whole genome shotgun sequencing is the fastest and most cost-effective method for sequencing long stretches of DNA, and most genomes, including the human genome, have been sequenced by this method.

KEY CONCEPTS of Section 5.2

DNA Cloning and Characterization

- In DNA cloning, recombinant DNA molecules are formed in vitro by inserting DNA fragments into vector DNA molecules. The recombinant DNA molecules are then introduced into host cells, where they replicate, producing large numbers of recombinant DNA molecules.
- Restriction enzymes (endonucleases) typically cut DNA at specific 4- to 8-bp palindromic sequences, producing defined

EXPERIMENTAL FIGURE 5-25 Two strategies for assembling whole genome sequences. One method (*left*) depends on isolating and assembling a set of cloned DNA segments that span the genome. This can be done by matching cloned segments by hybridization or by alignment of restriction-site maps. The DNA sequence of the ordered clones can then be assembled into a complete genomic sequence. The alternative method (*right*) depends on the relative ease of automated DNA sequencing and bypasses the laborious step of ordering the library. By sequencing enough random library clones so that each segment of the genome is represented from 3 to 10 times, it is possible to reconstruct the genomic sequence by computer alignment of the very large number of sequence fragments.

fragments that often have self-complementary single-stranded tails (sticky ends).

- Two restriction fragments with complementary ends can be joined with DNA ligase to form a recombinant DNA molecule (see Figure 5-12).
- *E. coli* cloning vectors are small circular DNA molecules (plasmids) that include three functional regions: an origin of replication, a drug-resistance gene, and a site where a DNA fragment can be inserted. Transformed cells carrying a vector grow into colonies on the selection medium (see Figure 5-13).
- A cDNA library is a set of cDNA clones prepared from the mRNAs isolated from a particular type of tissue. A genomic library is a set of clones carrying restriction fragments produced by cleavage of the entire genome.
- In cDNA cloning, expressed mRNAs are reverse-transcribed into complementary DNAs, or cDNAs. By a series of reactions,

single-stranded cDNAs are converted into double-stranded DNAs, which can then be ligated into a plasmid vector (see Figure 5-15).

- A particular cloned DNA fragment within a library can be detected by hybridization to a radiolabeled oligonucleotide whose sequence is complementary to a part of the fragment (see Figure 5-16).
- Shuttle vectors that replicate in both yeast and *E. coli* can be used to construct a yeast genomic library. Specific genes can be isolated by their ability to complement the corresponding mutant genes in yeast cells (see Figure 5-17).
- Long cloned DNA fragments can be cleaved with restriction enzymes, producing smaller fragments that are then separated by gel electrophoresis and subcloned into plasmid vectors prior to sequencing or experimental manipulation.
- The polymerase chain reaction (PCR) permits exponential amplification of a specific segment of DNA from just a single initial template DNA molecule if the sequence flanking the DNA region to be amplified is known (see Figure 5-20).
- PCR is a highly versatile method that can be programmed to amplify a specific genomic DNA sequence, a cDNA, or a sequence at the junction between a transposable element and flanking chromosomal sequences.
- DNA fragments up to about 100 nucleotides long are sequenced by generating clusters of identical molecules by PCR and imaging fluorescently labeled nucleotide precursors incorporated by DNA polymerase (see Figures 5-23 and 5-24).
- Whole genome sequences can be assembled from the sequences of a large number of overlapping clones from a genomic library (see Figure 5-25).

5.3 Using Cloned DNA Fragments to Study Gene Expression

In the last section, we described the basic techniques for using recombinant DNA technology to isolate specific DNA clones, and ways in which the clones can be further characterized. Now we consider how an isolated DNA clone can be used to study gene expression. We discuss several widely used general techniques that rely on nucleic acid hybridization to elucidate when and where genes are expressed, as well as methods for generating large quantities of protein and otherwise manipulating amino acid sequences to determine their expression patterns, structure, and function. More specific applications of all these basic techniques are examined in the following sections.

Hybridization Techniques Permit Detection of Specific DNA Fragments and mRNAs

Two very sensitive methods for detecting a particular DNA or RNA sequence within a complex mixture combine sepa-

ration by gel electrophoresis and hybridization with a complementary DNA probe that is either radioactively or fluorescently labeled. A third method involves hybridizing labeled probes directly onto a prepared tissue sample. We will encounter references to all three of these techniques, which have numerous applications, in other chapters.

Southern Blotting The first hybridization technique to detect DNA fragments of a specific sequence is known as **Southern blotting**, after its originator E. M. Southern. This technique is capable of detecting a single specific restriction fragment in the highly complex mixture of fragments produced by cleavage of the entire human genome with a restriction enzyme. When such a complex mixture is subjected to gel electrophoresis, so many different fragments of nearly the same length are present it is not possible to resolve any particular DNA fragments as a discrete band on the gel. Nevertheless, it is possible to identify a particular fragment migrating as a band on the gel by its ability to hybridize to a specific DNA probe. To accomplish this, the restriction fragments present in the gel are denatured with alkali and transferred onto a nitrocellulose filter or nylon membrane by blotting (Figure 5-26). This procedure preserves the distribution of the fragments in the gel, creating a replica of the gel on the filter. (The blot is used because probes do not readily diffuse into the original gel.) The filter then is incubated under hybridization conditions with a specific labeled DNA probe, which usually is generated from a cloned restriction fragment. The DNA restriction fragment that is complementary to the probe hybridizes, and its location on the filter can be revealed by autoradiography for a radiolabeled probe or by fluorescent imaging for a fluorescently labeled probe. Although PCR is most commonly used to detect the presence of a particular sequence in a complex mixture, Southern blotting is still useful for reconstructing the relationship between genomic sequences that are too far apart to be amplified by PCR in a single reaction.

Northern Blotting One of the most basic ways to characterize a cloned gene is to determine when and where in an organism the gene is expressed. Expression of a particular gene can be followed by assaying for the corresponding mRNA by **Northern blotting**, named, in a play on words, after the related method of Southern blotting. An RNA sample, often the total cellular RNA, is denatured by treatment with an agent such as formaldehyde that disrupts the hydrogen bonds between base pairs, ensuring that all the RNA molecules have an unfolded, linear conformation. The individual RNAs are separated according to size by gel electrophoresis and transferred to a nitrocellulose filter to which the extended denatured RNAs adhere. As in Southern blotting, the filter then is exposed to a labeled DNA probe that is complementary to the gene of interest; finally, the labeled filter is subjected to autoradiography. Because the amount of a specific RNA in a sample can be estimated from a Northern blot, the procedure is widely used to compare the amounts of a particular mRNA in cells under different conditions (Figure 5-27).

EXPERIMENTAL FIGURE 5-26 Southern blot technique can detect a specific DNA fragment in a complex mixture of restriction fragments. The diagram depicts three different restriction fragments in the gel, but the procedure can be applied to a mixture of millions of

DNA fragments. Only fragments that hybridize to a labeled probe will give a signal on an autoradiogram. A similar technique called Northern blotting detects specific mRNAs within a mixture. [See E. M. Southern, 1975, *J. Mol. Biol.* **98**:508.]

In Situ Hybridization Northern blotting requires extracting the mRNA from a cell or mixture of cells, which means that the cells are removed from their normal location within an organism or tissue. As a result, the location of a cell and its relation to its neighbors is lost. To retain such positional information in precise studies of gene expression, a whole or sectioned tissue or even a whole permeabilized embryo may be

subjected to **in situ hybridization** to detect the mRNA encoded by a particular gene. This technique allows gene transcription to be monitored in both time and space (Figure 5-28).

DNA Microarrays Can Be Used to Evaluate the Expression of Many Genes at One Time

Monitoring the expression of thousands of genes simultaneously is possible with **DNA microarray** analysis, another technique based on the concept of nucleic acid hybridization. A DNA microarray consists of an organized array of thousands of individual, closely packed gene-specific sequences attached to the surface of a glass microscope slide. By coupling microarray analysis with the results from genome sequencing projects, researchers can analyze the global patterns of gene expression of an organism during specific physiological responses or developmental processes.

Preparation of DNA Microarrays In one method for preparing microarrays, an ≈ 1 -kb part of the coding region of each gene analyzed is individually amplified by the PCR. A robotic device is used to apply each amplified DNA sample to the surface of a glass microscope slide, which then is chemically processed to permanently attach the DNA sequences to the glass surface and to denature them. A typical array might contain ≈ 6000 spots of DNA in a 2×2 -cm grid.

In an alternative method, multiple DNA oligonucleotides, usually at least 20 nucleotides in length, are synthesized from an initial nucleotide that is covalently bound to the surface of a glass slide. The synthesis of an oligonucleotide of specific sequence can be programmed in a small region on the surface of the slide. Several oligonucleotide sequences from a single gene are thus synthesized in neighboring regions of the slide to analyze expression of that gene. With this method, oligonucleotides representing thousands of genes can be produced on a single glass slide. Because the methods for constructing these arrays of synthetic oligonucleotides were adapted from

EXPERIMENTAL FIGURE 5-27 Northern blot analysis reveals increased expression of β -globin mRNA in differentiated erythroleukemia cells. The total mRNA in extracts of erythroleukemia cells that were growing but uninduced and in cells induced to stop growing and allowed to differentiate for 48 hours or 96 hours was analyzed by Northern blotting for β -globin mRNA. The density of a band is proportional to the amount of mRNA present. The β -globin mRNA is barely detectable in uninduced cells (UN lane) but increases more than 1000-fold by 96 hours after differentiation is induced. [Courtesy of L. Kole.]

EXPERIMENTAL FIGURE 5-28 In situ hybridization can detect activity of specific genes in whole and sectioned embryos. The specimen is permeabilized by treatment with detergent and a protease to expose the mRNA to the probe. A DNA or RNA probe, specific for the mRNA of interest, is made with nucleotide analogs containing chemical groups that can be recognized by antibodies. After the permeabilized specimen has been incubated with the probe under conditions that promote hybridization, the excess probe is removed with a series of washes. The specimen is then incubated in a solution containing an antibody that binds to the probe. This antibody is covalently joined to a reporter enzyme (e.g., horseradish peroxidase or alkaline phosphatase) that produces a colored reaction product. After excess antibody

has been removed, substrate for the reporter enzyme is added. A colored precipitate forms where the probe has hybridized to the mRNA being detected. (a) A whole mouse embryo at about 10 days of development probed for *Sonic hedgehog* mRNA. The stain marks the notochord (red arrow), a rod of mesoderm running along the future spinal cord. (b) A section of a mouse embryo similar to that in part (a). The dorsal/ventral axis of the neural tube (NT) can be seen, with the *Sonic hedgehog*-expressing notochord (red arrow) below it and the endoderm (blue arrow) still farther ventral. [Courtesy of L. Milenkovic and M. P. Scott.]

methods for manufacturing microscopic integrated circuits used in computers, these types of oligonucleotide microarrays are often called *DNA chips*.

Using Microarrays to Compare Gene Expression Under Different Conditions The initial step in a microarray expression study is to prepare fluorescently labeled cDNAs corresponding to the mRNAs expressed by the cells under study. When the cDNA preparation is applied to a microarray, spots representing genes that are expressed will hybridize under appropriate conditions to their complementary cDNAs in the labeled probe mix and can subsequently be detected in a scanning laser microscope.

Figure 5-29 depicts how this method can be applied to examine the changes in gene expression observed after starved human fibroblasts are transferred to a rich, serum-containing growth medium. In this type of experiment, the separate cDNA preparations from starved and serum-grown fibroblasts are labeled with differently colored fluorescent dyes. A DNA array comprising 8600 mammalian genes then is incubated with a mixture containing equal amounts of the two cDNA preparations under hybridization conditions. After unhybridized cDNA is washed away, the intensity of green and red fluorescence at each DNA spot is measured using a fluorescence microscope and stored in computer files under the name of each gene according to its known position on the slide. The relative intensities of red and green fluorescence signals at each spot are a measure of the relative level of expression of that gene in response to serum. Genes that

are not transcribed under these growth conditions give no detectable signal. Genes that are transcribed at the same level under both conditions will hybridize equally to both red- and green-labeled cDNA preparations. Microarray analysis of gene expression in fibroblasts showed that transcription of about 500 of the 8600 genes examined changed substantially after addition of serum.

Cluster Analysis of Multiple Expression Experiments Identifies Co-regulated Genes

Firm conclusions rarely can be drawn from a single microarray experiment about whether genes that exhibit similar changes in expression are co-regulated and hence likely to be closely related functionally. For example, many of the observed differences in gene expression just described in fibroblasts could be indirect consequences of the many different changes in cell physiology that occur when cells are transferred from one medium to another. In other words, genes that appear to be co-regulated in a single microarray expression experiment may undergo changes in expression for very different reasons and may actually have very different biological functions. A solution to this problem is to combine the information from a set of expression array experiments to find genes that are similarly regulated under a variety of conditions or over a period of time.

This more informative use of multiple expression array experiments is illustrated by examining the relative expression of the 8600 genes at different times after serum addition,

TECHNIQUE ANIMATION: Synthesizing an Oligonucleotide Array
TECHNIQUE ANIMATION: Screening for Patterns of Gene Expression

EXPERIMENTAL FIGURE 5-29 DNA microarray analysis can reveal differences in gene expression in fibroblasts under different experimental conditions. (a) In this example, cDNA prepared from mRNA isolated from fibroblasts either starved for serum or after serum addition is labeled with different fluorescent dyes. A microarray composed of DNA spots representing 8600 mammalian genes is exposed to an equal mixture of the two cDNA preparations under hybridization conditions. The ratio of the intensities of red and green fluorescence over each spot, detected with a scanning confocal laser microscope, indicates the relative expression of each gene in response to serum. (b) A micrograph of a small segment of an actual DNA microarray. Each spot in this 16×16 array contains DNA from a different gene hybridized to control and experimental cDNA samples labeled with red and green fluorescent dyes. (A yellow spot indicates equal hybridization of green and red fluorescence, indicating no change in gene expression.) [Part (b) Alfred Pasieka/Photo Researchers, Inc.]

generating more than 10^4 individual pieces of data. A computer program, related to the one used to determine the relatedness of different protein sequences, can organize these data and cluster genes that show similar expression over the time course after serum addition. Remarkably, such *cluster analysis* groups sets of genes whose encoded proteins participate in a common cellular process, such as cholesterol biosynthesis or the cell cycle (Figure 5-30).

In the future, microarray analysis will be a powerful diagnostic tool in medicine. For instance, particular sets of mRNAs have been found to distinguish tumors with a poor prognosis from those with a good prognosis. Previously indistinguishable disease variations are now detectable. Analysis of tumor biopsies for these distinguishing mRNAs will help physicians to select the most appropriate treatment. As more patterns of gene expression characteristic of various diseased tissues are recognized, the diagnostic use of DNA microarrays will be extended to other conditions. ■

***E. coli* Expression Systems Can Produce Large Quantities of Proteins from Cloned Genes**

Many protein hormones and other signaling or regulatory proteins are normally expressed at very low concentrations, precluding their isolation and purification in large quantities by standard biochemical techniques. Widespread therapeutic use of such proteins, as well as basic research on their structure and functions, depends on efficient procedures for producing them in large amounts at reasonable cost. Recombinant DNA techniques that turn *E. coli* cells into factories for synthesizing low-abundance proteins now are used to commercially produce granulocyte-colony-stimulating factor (G-CSF), insulin, growth hormone, and other human proteins with therapeutic uses. For example, G-CSF stimulates the production of granulocytes, the phagocytic white blood

EXPERIMENTAL FIGURE 5-30 Cluster analysis of data from multiple microarray expression experiments can identify co-regulated genes. The expression of 8600 mammalian genes was detected by microarray analysis at time intervals over a 24-hour period after serum-starved fibroblasts were provided with serum. The cluster diagram shown here is based on a computer algorithm that groups genes showing similar changes in expression compared with a serum-starved control sample over time. Each column of colored boxes represents a single gene, and each row represents a time point. A red box indicates an increase in expression relative to the control; a green box, a decrease in expression; and a black box, no significant change in

expression. The “tree” diagram at the top shows how the expression patterns for individual genes can be organized in a hierarchical fashion to group together the genes with the greatest similarity in their patterns of expression over time. Five clusters of coordinately regulated genes were identified in this experiment, as indicated by the bars at the bottom. Each cluster contains multiple genes whose encoded proteins function in a particular cellular process: cholesterol biosynthesis (A), the cell cycle (B), the immediate-early response (C), signaling and angiogenesis (D), and wound healing and tissue remodeling (E). cells critical to defense against bacterial infections. Administration of G-CSF to cancer patients helps offset the reduction in granulocyte production caused by chemotherapeutic agents, thereby protecting patients against serious infection while they are receiving chemotherapy. ■

The first step in producing large amounts of a low-abundance protein is to obtain a cDNA clone encoding the full-length protein by methods discussed previously. The second step is to engineer plasmid vectors that will express large amounts of the encoded protein when it is inserted into *E. coli* cells. The key to designing such expression vectors is inclusion of a promoter, a DNA sequence from which transcription of the cDNA can begin. Consider, for example, the relatively simple system for expressing G-CSF shown in Figure 5-31. In this

EXPERIMENTAL FIGURE 5-31 Some eukaryotic proteins can be produced in *E. coli* cells from plasmid vectors containing the *lac* promoter. (a) The plasmid expression vector contains a fragment of the *E. coli* chromosome containing the *lac* promoter and the neighboring *lacZ* gene. In the presence of the lactose analog IPTG, RNA polymerase normally transcribes the *lacZ* gene, producing *lacZ* mRNA, which is translated into the encoded protein, β -galactosidase. (b) The *lacZ* gene can be cut out of the expression vector with restriction enzymes and replaced by a cloned cDNA, in this case one encoding granulocyte-colony-stimulating factor (G-CSF). When the resulting plasmid is transformed into *E. coli* cells, addition of IPTG and subsequent transcription from the *lac* promoter produce G-CSF mRNA, which is translated into G-CSF protein.

case, G-CSF is expressed in *E. coli* transformed with plasmid vectors that contain the *lac* promoter adjacent to the cloned cDNA encoding G-CSF. Transcription from the *lac* promoter occurs at high rates only when lactose, or a lactose analog such as isopropylthiogalactoside (IPTG), is added to the culture medium. Even larger quantities of a desired protein can be produced in more complicated *E. coli* expression systems.

To aid in purification of a eukaryotic protein produced in an *E. coli* expression system, researchers often modify the cDNA encoding the recombinant protein to facilitate its separation from endogenous *E. coli* proteins. A commonly used modification of this type is to add a short nucleotide sequence to the end of the cDNA, so that the expressed protein will have six histidine residues at the C-terminus. Proteins modified in this way bind tightly to an affinity matrix that contains chelated nickel atoms, whereas most *E. coli* proteins will not bind to such a matrix. The bound proteins can be released from the nickel atoms by decreasing the pH of the surrounding medium. In most cases, this procedure yields a pure recombinant protein that is functional, since addition of short amino acid sequences to either the C-terminus or the N-terminus of a protein usually does not interfere with the protein's biochemical activity.

Plasmid Expression Vectors Can Be Designed for Use in Animal Cells

Although bacterial expression systems can be used successfully to create large quantities of some proteins, bacteria cannot be used in all cases. Many experiments to examine the function of a protein in an appropriate cellular context require expression of a genetically modified protein in cultured animal cells. Genes are cloned into specialized eukaryotic expression vectors and are introduced into cultured animal cells by a process called **transfection**. Two common methods for transfecting animal cells differ in whether the recombinant vector DNA is or is not integrated into the host-cell genomic DNA.

In both methods, cultured animal cells must be treated to facilitate their initial uptake of the recombinant plasmid vector. This can be done by exposing cells to a preparation of lipids that penetrate the plasma membrane, increasing its permeability to DNA. Alternatively, subjecting cells to a brief electric shock of several thousand volts, a technique known as *electroporation*, makes them transiently permeable to DNA. Usually the plasmid DNA is added in sufficient concentration to ensure that a large proportion of the cultured cells will receive at least one copy of the plasmid DNA. Researchers have also harnessed viruses for their use in the laboratory; viruses can be modified to contain DNA of interest, which is then introduced into host cells by simply infecting them with the recombinant virus.

Transient Transfection The simplest of the two expression methods, called *transient transfection*, employs a vector similar

to the yeast shuttle vectors described previously. For use in mammalian cells, plasmid vectors are engineered also to carry an origin of replication derived from a virus that infects mammalian cells, a strong promoter recognized by mammalian RNA polymerase, and the cloned cDNA encoding the protein to be expressed adjacent to the promoter (Figure 5-32a). Once such a plasmid vector enters a mammalian cell, the viral origin of replication allows it to replicate efficiently, generating numerous plasmids from which the protein is expressed. However, during cell division such plasmids are not faithfully segregated into both daughter cells and in time a substantial fraction of the cells in a culture will not contain a plasmid, hence the name *transient transfection*.

Stable Transfection (Transformation) If an introduced vector integrates into the genome of the host cell, the genome is permanently altered and the cell is said to be *transformed*. Integration most likely is accomplished by mammalian enzymes that normally function in DNA repair and recombination. A commonly used selectable marker is the gene for neomycin phosphotransferase (designated *neo^r*), which confers resistance to a toxic compound chemically related to neomycin known as G-418. The basic procedure for expressing a cloned cDNA by *stable transfection* is outlined in Figure 5-32b. Only those cells that have integrated the expression vector into the host chromosome will survive and give rise to a clone in the presence of a high concentration of G-418. Because integration occurs at random sites in the genome, individual transformed clones resistant to G-418 will differ in their rates of transcribing the inserted cDNA. Therefore, the stable transfectants usually are screened to identify those that produce the protein of interest at the highest levels.

Retroviral Expression Systems Researchers have exploited the basic mechanisms used by viruses for introduction of genetic material into animal cells and subsequent insertion into chromosomal DNA to greatly increase the efficiency by which a modified gene can be stably expressed in animal cells. An example of one such viral expression is derived from a class of retroviruses known as *lentiviruses*. As shown in Figure 5-33, three different plasmids, introduced into cells by transient transfection, are used to produce recombinant lentivirus particles suitable for efficient introduction of a cloned gene into target animal cells. The first plasmid, known as the *vector plasmid*, contains a cloned gene of interest next to a selectable marker such as *neo^r* flanked by lentivirus LTR sequences. As described in Chapter 6, viral LTR sequences direct synthesis of a viral RNA molecule that on introduction into a virally infected target cell can be copied into DNA by reverse transcription and then integrated into chromosomal DNA. A second plasmid known as the packaging plasmid carries all the viral genes, except for the major viral envelope protein, necessary for packaging LTR-containing viral RNA into a functional lentivirus particle. The final plasmid allows expression of a viral envelope protein that when incorporated into a recombinant lentivirus will allow the resulting hybrid virus particles to infect a

(a) Transient transfection

(b) Stable transfection (transformation)

EXPERIMENTAL FIGURE 5-32 Transient and stable transfection with specially designed plasmid vectors permits expression of cloned genes in cultured animal cells. Both methods employ plasmid vectors that contain the usual elements—ORI, selectable marker (e.g., *amp^r*), and polylinker—that permit propagation in *E. coli* and insertion of a cloned cDNA with an adjacent animal promoter. For simplicity, these elements are not depicted. (a) In transient transfection, the plasmid vector contains an origin of replication for a virus that can replicate in the cultured animal cells. Since the vector is not incorporated into the genome of the cultured cells, production of the cDNA-encoded protein continues only for a limited time. (b) In stable transfection, the vector carries a selectable marker such as *neo^r*, which confers resistance to G-418. The relatively few transfected animal cells that integrate the exogenous DNA into their genomes are selected on medium containing G-418. Because the vector is integrated into the genome, these stably transfected, or transformed, cells will continue to produce the cDNA-encoded protein as long as the culture is maintained. See the text for discussion.

cells with a stably integrated cloned gene and *neo^r* marker can be selected for by resistance to G-418. Many of the techniques for inactivating the function of specific genes (see Section 5.5) require that an entire population of cultured cells be genetically modified simultaneously. Engineered lentiviruses are particularly useful for such experiments because they infect cells with very high efficiency such that every cell in a population will receive at least one copy of the lentivirus-borne plasmid.

Gene and Protein Tagging Expression vectors can provide a way to study the expression and intracellular localization of eukaryotic proteins. This method often relies on using a reporter protein such as *green fluorescent protein (GFP)* that can conveniently be detected in cells. Here we describe two ways to create a hybrid gene that connects expression of the reporter protein to the protein of interest. When the hybrid gene is reintroduced into cells, either by transfection with a plasmid expression vector containing the modified gene or by creation of a transgenic animal as described in Section 5.5, the expression of the reporter protein can be used to determine where and when a gene is expressed. This method provides similar data to in situ hybridization experiments described previously but often with greater resolution and sensitivity.

Figure 5-34 illustrates the use of two different types of GFP-tagging experiments to study the expression of an odorant receptor protein in *C. elegans*. When the promoter for the odorant receptor is linked directly to the coding sequence of GFP in a configuration usually known as a *promoter-fusion*, GFP is expressed in specific neurons, filling the cytoplasm of those neurons. In contrast, when the hybrid gene is constructed by linking GFP to the coding sequence of the receptor, the resulting *protein-fusion* can be localized by GFP fluorescence at the distal cilia in sensory neurons, the site at which the receptor protein is normally located.

desired target cell type. A common envelope protein used in this context is the glycoprotein of the vesicular stomatitis virus (VSV-G protein), which can readily replace the normal lentivirus envelope protein on the surface of completed virus particles and will allow the resulting virus particles to infect a wide variety of mammalian cell types, including hematopoietic stem cells, neurons, and muscle and liver cells. After cell infection, the cloned gene flanked by viral LTR sequences is reverse-transcribed into DNA, which is transported into the nucleus and then integrated into the host genome. If necessary, as in the case for stable transfection,

EXPERIMENTAL FIGURE 5-33 Retroviral vectors can be used for efficient integration of cloned genes into the mammalian genome. See the text for discussion.

An alternative to GFP tagging for detecting the intracellular location of a protein is to modify the gene of interest by fusing it with a short DNA sequence that encodes a short stretch of amino acids recognized by a known monoclonal

antibody. Such a short peptide that can be bound by an antibody is called an epitope; hence this method is known as *epitope tagging*. After transfection with a plasmid expression vector containing the modified gene, the expressed epitope-tagged form of the protein can be detected by immunofluorescence labeling of the cells with the monoclonal antibody specific for the epitope. The choice of whether to use a short epitope or GFP to tag a given protein often depends on what types of modification a cloned gene can tolerate and still remain functional.

(a) Promoter-fusion; ODR10 promoter fused to GFP

(b) Protein-fusion; ODR10-GFP fusion protein

10 μ m

EXPERIMENTAL FIGURE 5-34 Gene and protein tagging facilitate cellular localization of proteins expressed from cloned genes.

In this experiment, the gene encoding a chemical odorant receptor, Odr10, of *C. elegans* was fused to the gene sequence for green fluorescent protein (GFP). (a) A promoter-fusion was generated by linking GFP to the promoter and the first four amino acid codons of Odr10. This protein is expressed in the cytoplasm of specific sensory neurons in the head of *C. elegans*. Note that the cell body (dashed arrow) and sensory dendrites (solid arrow) are fluorescently labeled. (b) A protein-fusion was constructed by linking GFP to the end of the full-length Odr10 coding sequence. In this case, the Odr10-GFP fusion protein is targeted to the membrane at the tip of the sensory neurons and is only apparent at the distal end of the sensory cilia. The observed distribution can be inferred to reflect the normal location of Odr10 protein in specific neurons. Because the promoter-fusion shown in (a) lacks the Odr10 localization sequences, the expressed GFP fills the entire cell cytoplasm rather than being localized just to distal tip of the sensory cilia. [P. Sengupta et al., 1996, *Cell* 84:899 (derived from Figures 4 and 5).]

KEY CONCEPTS of Section 5.3

Using Cloned DNA Fragments to Study Gene Expression

- Southern blotting can detect a single, specific DNA fragment within a complex mixture by combining gel electrophoresis, transfer (blotting) of the separated bands to a filter, and hybridization with a complementary radiolabeled DNA probe (see Figure 5-26). The similar technique of Northern blotting detects a specific RNA within a mixture.
- The presence and distribution of specific mRNAs can be detected in living cells by *in situ* hybridization.
- DNA microarray analysis simultaneously detects the relative level of expression of thousands of genes in different types of cells or in the same cells under different conditions (see Figure 5-29).
- Cluster analysis of the data from multiple microarray expression experiments can identify genes that are similarly regulated under various conditions. Such co-regulated genes commonly encode proteins that have biologically related functions.
- Expression vectors derived from plasmids allow the production of abundant amounts of a protein from a cloned gene.
- Eukaryotic expression vectors can be used to express cloned genes in yeast or mammalian cells. An important application of these methods is the tagging of proteins with GFP or an epitope for antibody detection.

5.4 Locating and Identifying Human Disease Genes

 Inherited human diseases are the phenotypic consequence of defective human genes. Table 5-2 lists several of the most commonly occurring inherited diseases. Although a “disease” gene may result from a new mutation that arose in the preceding generation, most cases of inherited diseases are caused by preexisting mutant alleles that have been passed from one generation to the next for many generations. ■

The typical first step in deciphering the underlying cause for any inherited human disease is to identify the affected gene and its encoded protein. Comparison of the sequences of a disease gene and its product with those of genes and proteins whose sequence and function are known can provide clues to the molecular and cellular cause of the disease. Historically, researchers have used whatever phenotypic clues might be relevant to make guesses about the molecular basis of inherited diseases. An early example of successful guesswork was the hypothesis that sickle-cell anemia, known to be a disease of blood cells, might be caused by defective hemoglobin. This idea led to identification of a specific amino acid substitution in hemoglobin that causes polymerization of the

defective hemoglobin molecules, causing the sickle-like deformation of red blood cells in individuals who have inherited two copies of the *Hb^s* allele for sickle-cell hemoglobin.

Most often, however, the genes responsible for inherited diseases must be found without any prior knowledge or reasonable hypotheses about the nature of the affected gene or its encoded protein. In this section, we will see how human geneticists can find the gene responsible for an inherited disease by following the segregation of the disease in families. The segregation of the disease can be correlated with the segregation of many other genetic markers, eventually leading to identification of the chromosomal position of the affected gene. This information, along with knowledge of the sequence of the human genome, can ultimately allow the affected gene and the disease-causing mutations to be pinpointed.

Monogenic Diseases Show One of Three Patterns of Inheritance

Human genetic diseases that result from mutation in one specific gene are referred to as *monogenic diseases* and display different inheritance patterns depending on the nature and chromosomal location of the alleles that cause them. One characteristic pattern is that exhibited by a dominant allele in an autosome (that is, one of the 22 human chromosomes that is not a sex chromosome). Because an *autosomal dominant* allele is expressed in the heterozygote, usually at least one of the parents of an affected individual will also have the disease. It is often the case that the diseases caused by dominant alleles appear later in life after the reproductive age. If this were not the case, natural selection would have eliminated the allele during human evolution. An example of an autosomal dominant disease is Huntington’s disease, a neural degenerative disease that generally strikes in mid- to late life. If either parent carries a mutant *HD* allele, each of his or her children (regardless of sex) has a 50 percent chance of inheriting the mutant allele and being affected (Figure 5-35a).

A recessive allele in an autosome exhibits a quite different segregation pattern. For an *autosomal recessive* allele, both parents must be heterozygous *carriers* of the allele in order for their children to be at risk of being affected with the disease. Each child of heterozygous parents has a 25 percent chance of receiving both recessive alleles and thus being affected, a 50 percent chance of receiving one normal and one mutant allele and thus being a carrier, and a 25 percent chance of receiving two normal alleles. A clear example of an autosomal recessive disease is cystic fibrosis, which results from a defective chloride-channel gene known as *CFTR* (Figure 5-35b). Related individuals (e.g., first or second cousins) have a relatively high probability of being carriers for the same recessive alleles. Thus children born to related parents are much more likely than those born to unrelated parents to be homozygous for, and therefore affected by, an autosomal recessive disorder.

The third common pattern of inheritance is that of an *X-linked recessive* allele. A recessive allele on the X chromo-

TABLE 5-2 Common Inherited Human Diseases

Disease	Molecular and Cellular Defect	Incidence
Autosomal Recessive		
Sickle-cell anemia	Abnormal hemoglobin causes deformation of red blood cells, which can become lodged in capillaries; also confers resistance to malaria.	1/625 of sub-Saharan African origin
Cystic fibrosis	Defective chloride channel (CFTR) in epithelial cells leads to excessive mucus in lungs.	1/2500 of European origin
Phenylketonuria (PKU)	Defective enzyme in phenylalanine metabolism (tyrosine hydroxylase) results in excess phenylalanine leading to mental retardation, unless restricted by diet.	1/10,000 of European origin
Tay-Sachs disease	Defective hexosaminidase enzyme leads to accumulation of excess sphingolipids in the lysosomes of neurons, impairing neural development.	1/1000 eastern European Jews
Autosomal Dominant		
Huntington's disease	Defective neural protein (huntingtin) may assemble into aggregates, causing damage to neural tissue.	1/10,000 of European origin
Hypercholesterolemia	Defective LDL receptor leads to excessive cholesterol in blood and early heart attacks.	1/122 French Canadians
X-Linked Recessive		
Duchenne muscular dystrophy (DMD)	Defective cytoskeletal protein dystrophin leads to impaired muscle function.	1/3500 males
Hemophilia A	Defective blood clotting factor VIII leads to uncontrolled bleeding.	1–2/10,000 males

some will most often be expressed in males, who receive only one X chromosome from their mother, but not in females, who receive an X chromosome from both their mother and their father. This leads to a distinctive sex-linked segregation pattern where the disease is exhibited much more frequently in males than in females. For example, Duchenne muscular dystrophy (DMD), a muscle degenerative disease that specifically affects males, is caused by a recessive allele on the X chromosome. DMD exhibits the typical sex-linked segregation pattern in which mothers who are heterozygous and therefore phenotypically normal can act as carriers, transmitting the DMD allele and therefore the disease to 50 percent of their male progeny (Figure 5-35c).

DNA Polymorphisms Are Used as Markers for Linkage-Mapping of Human Mutations

Once the mode of inheritance has been determined, the next step in determining the position of a disease allele is to genetically map its position with respect to known genetic

markers using the basic principle of genetic linkage as described in Section 5.1. The presence of many different already mapped genetic traits, or markers, distributed along the length of a chromosome facilitates the mapping of a new mutation: one can assess its possible linkage to these marker genes in appropriate crosses. The more markers that are available, the more precisely a mutation can be mapped. The density of genetic markers needed for a high-resolution human genetic map is about one marker every 5 centimorgans (cM) (as discussed previously, one genetic map unit, or centimorgan, is defined as the distance between two positions along a chromosome that results in one recombinant individual in 100 progeny). Thus a high-resolution genetic map requires 25 or so genetic markers of known position spread along the length of each human chromosome.

In the experimental organisms commonly used in genetic studies, numerous markers with easily detectable phenotypes are available for genetic mapping of mutations. This is not the case for mapping genes whose mutant alleles are associated with inherited diseases in humans. However, recombinant

FIGURE 5-35 Three common inheritance patterns for human genetic diseases. Wild-type autosomal (A) and sex chromosomes (X and Y) are indicated by superscript plus signs. (a) In an autosomal dominant disorder such as Huntington's disease, only one mutant allele is needed to confer the disease. If either parent is heterozygous for the mutant *HD* allele, his or her children have a 50 percent chance of inheriting the mutant allele and getting the disease. (b) In an autosomal recessive disorder such as cystic fibrosis, two mutant alleles must be present to confer the disease. Both parents must be heterozygous carriers of the mutant *CFTR* gene for their children to be at risk of being affected or being carriers. (c) An X-linked recessive disease such as Duchenne muscular dystrophy is caused by a recessive mutation on the X chromosome and exhibits the typical sex-linked segregation pattern. Males born to mothers heterozygous for a mutant *DMD* allele have a 50 percent chance of inheriting the mutant allele and being affected. Females born to heterozygous mothers have a 50 percent chance of being carriers.

DNA technology has made available a wealth of useful DNA-based molecular markers. Because most of the human genome does not code for protein, a large amount of sequence variation exists between individuals. Indeed, it has been estimated that nucleotide differences between unrelated individuals can be detected on an average of every 10^3 nucleotides. If these variations in DNA sequence, referred to as *DNA polymorphisms*, can be followed from one generation to the next, they can serve as genetic markers for linkage studies. Currently, a panel of as many as 10^4 different known polymorphisms whose locations have been mapped in the human genome is used for genetic linkage studies in humans.

Single-nucleotide polymorphisms (SNPs) constitute the most abundant type and are therefore useful for constructing genetic maps of maximum resolution (Figure 5-36). Another useful type of DNA polymorphism consists of a variable

EXPERIMENTAL FIGURE 5-36 Single-Nucleotide Polymorphisms (SNPs) can be followed like genetic markers. Hypothetical pedigree based on SNP analysis of the DNA from a region of a chromosome. In this family, the SNP exists as an A, T, or C nucleotide. Each individual has two alleles: some contain an A on both chromosomes, and others are heterozygous at this site. Circles indicate females; squares indicate males. Blue indicates unaffected individuals; orange indicates individuals with the trait. Analysis reveals that the trait segregates with a C at the SNP.

number of repetitions of a one-, two-, or three-base sequence. Such polymorphisms, known as simple-sequence repeats (SSRs) or *microsatellites*, presumably are formed by recombination or a slippage mechanism of either the template or newly synthesized strands during DNA replication. A useful property of SSRs is that different individuals will often have different numbers of repeats. The existence of multiple versions of an SSR makes it more likely to produce an informative segregation pattern in a given pedigree and therefore to be of more general use in mapping the positions of disease genes. These polymorphisms can be detected by PCR amplification and DNA sequencing.

Linkage Studies Can Map Disease Genes with a Resolution of About 1 Centimorgan

Without going into all the technical considerations, let's see how the allele conferring a particular dominant trait (e.g., familial hypercholesterolemia) might be mapped. The first step is to obtain DNA samples from all the members of a family containing individuals that exhibit the disease. The DNA from each affected and unaffected individual then is analyzed to determine the identity of a large number of known DNA polymorphisms (either SSR or SNP markers can be used). The segregation pattern of each DNA polymorphism within the family is then compared with the segregation of the disease under study to find those polymorphisms that tend to segregate along with the disease. Finally, computer analysis of the segregation data is used to calculate the likelihood of linkage between each DNA polymorphism and the disease-causing allele.

In practice, segregation data are collected from different families exhibiting the same disease and pooled. The more families exhibiting a particular disease that can be examined, the greater the statistical significance of evidence for linkage that can be obtained and the greater the precision with which

FIGURE 5-37 Linkage-disequilibrium studies of human populations can be used to map genes at high resolution. A new disease mutation will arise in the context of an ancestral chromosome among a set of polymorphisms known as the *haplotype* (indicated by red shading). After many generations, chromosomes that carry the disease mutation will also carry segments of the ancestral haplotype that have not been separated from the disease mutation by recombination. The blue segments of these chromosomes represent general haplotypes derived from the general population and not from the ancestral haplotype in which the mutation originally arose. This phenomenon is known as *linkage disequilibrium*. The position of the disease mutation can be located by scanning chromosomes containing the disease mutation for highly conserved polymorphisms corresponding to the ancestral haplotype.

the distance can be measured between a linked DNA polymorphism and a disease allele. Most family studies have a maximum of about 100 individuals in which linkage between a disease gene and a panel of DNA polymorphisms can be tested. This number of individuals sets the practical upper limit on the resolution of such a mapping study to about 1 centimorgan, or a physical distance of about 7.5×10^5 base pairs.

A phenomenon called *linkage disequilibrium* is the basis for an alternative strategy, which often can afford a higher degree of resolution in mapping studies. This approach depends on the particular circumstance in which a genetic disease commonly found in a particular population results from a single mutation that occurred many generations in the past. The DNA polymorphisms carried by this ancestral chromosome are collectively known as the *haplotype* of that chromosome. As the disease allele is passed from one generation to the next, only the polymorphisms that are closest to the disease gene will not be separated from it by recombination. After many generations, the region that contains the disease gene will be evident because this will be the only region of the chromosome that will carry the haplotype of the ancestral chromo-

some conserved through many generations (Figure 5-37). By assessing the distribution of specific markers in all the affected individuals in a population, geneticists can identify DNA markers tightly associated with the disease, thus localizing the disease-associated gene to a relatively small region. Under ideal circumstances, linkage disequilibrium studies can improve the resolution of mapping studies to less than 0.1 centimorgan. The resolving power of this method comes from the ability to determine whether a polymorphism and the disease allele were ever separated by a meiotic recombination event at any time since the disease allele first appeared on the ancestral chromosome—in some cases this can amount to finding markers that are so closely linked to the disease gene that even after hundreds of meioses, they have never been separated by recombination.

Further Analysis Is Needed to Locate a Disease Gene in Cloned DNA

Although linkage mapping can usually locate a human disease gene to a region containing about 10^3 base pairs, as many as 10 different genes may be located in a region of this size. The ultimate objective of a mapping study is to locate the gene within a cloned segment of DNA and then to determine the nucleotide sequence of this fragment. The relative scales of a chromosomal genetic map and physical maps corresponding to ordered sets of plasmid clones and the nucleotide sequence are shown in Figure 5-38.

One strategy for further localizing a disease gene within the genome is to identify mRNA encoded by DNA in the region of the gene under study. Comparison of gene expression in tissues from normal and affected individuals may suggest tissues in which a particular disease gene normally is expressed. For instance, a mutation that phenotypically affects muscle, but no other tissue, might be in a gene that is expressed only in muscle tissue. The expression of mRNA in both normal and affected individuals generally is determined by Northern blotting or in situ hybridization of labeled DNA or RNA to tissue sections. Northern blots, in situ hybridization, or microarray experiments permit comparison of both the level of expression and the size of mRNAs in mutant and wild-type tissues. Although the sensitivity of in situ hybridization is lower than that of Northern blot analysis, it can be very helpful in identifying an mRNA that is expressed at low levels in a given tissue but at very high levels in a subclass of cells within that tissue. An mRNA that is altered or missing in various individuals affected with a disease compared with wild-type individuals would be an excellent candidate for encoding the protein whose disrupted function causes that disease.

In many cases, point mutations that give rise to disease-causing alleles may result in no detectable change in the level of expression or electrophoretic mobility of mRNAs. Thus if comparison of the mRNAs expressed in normal and affected individuals reveals no detectable differences in the candidate mRNAs, a search for point mutations in the DNA regions

FIGURE 5-38 The relationship between the genetic and physical maps of a human chromosome. The diagram depicts a human chromosome analyzed at different levels of detail. The chromosome as a whole can be viewed in the light microscope when it is in a condensed state that occurs at metaphase, and the approximate location of specific sequences can be determined by fluorescence in situ hybridization (FISH). At the next level of detail, genetic traits can be

mapped relative to DNA-based genetic markers. Local segments of the chromosome can be analyzed at the level of DNA sequences identified by Southern hybridization or PCR. Finally, important genetic differences can be most precisely defined by differences in the nucleotide sequence of the chromosomal DNA. [Adapted from L. Hartwell et al., 2003, *Genetics: From Genes to Genomes*, 2d ed., McGraw-Hill.]

encoding the mRNAs is undertaken. Now that highly efficient methods for sequencing DNA are available, researchers frequently determine the sequence of candidate regions of DNA isolated from affected individuals to identify point mutations. The overall strategy is to search for a coding sequence that consistently shows possibly deleterious alterations in DNA from individuals that exhibit the disease. A limitation of this approach is that the region near the affected gene may carry naturally occurring polymorphisms unrelated to the gene of interest. Such polymorphisms, not functionally related to the disease, can lead to misidentification of the DNA fragment carrying the gene of interest. For this reason, the more mutant alleles available for analysis, the more likely that a gene will be correctly identified.

Many Inherited Diseases Result from Multiple Genetic Defects

Most of the inherited human diseases that are now understood at the molecular level are monogenic diseases; that is, a clearly discernible disease state is produced by a defect in a single gene. Monogenic diseases caused by mutation in one specific gene exhibit one of the characteristic inheritance patterns shown in Figure 5-35. The genes associated with most of the common monogenic diseases have already been mapped using DNA-based markers as described previously.

However, many other inherited diseases show more complicated patterns of inheritance, making the identification of the underlying genetic cause much more difficult. One type of

added complexity that is frequently encountered is *genetic heterogeneity*. In such cases, mutations in any one of multiple different genes can cause the same disease. For example, retinitis pigmentosa, which is characterized by degeneration of the retina usually leading to blindness, can be caused by mutations in any one of more than 60 different genes. In human linkage studies, data from multiple families usually must be combined to determine whether a statistically significant linkage exists between a disease gene and known molecular markers. Genetic heterogeneity such as that exhibited by retinitis pigmentosa can confound such an approach because any statistical trend in the mapping data from one family tends to be canceled out by the data obtained from another family with an unrelated causative gene.

Human geneticists used two different approaches to identify the many genes associated with retinitis pigmentosa. The first approach relied on mapping studies in exceptionally large single families that contained a sufficient number of affected individuals to provide statistically significant evidence for linkage between known DNA polymorphisms and a single causative gene. The genes identified in such studies showed that several of the mutations that cause retinitis pigmentosa lie within genes that encode abundant proteins of the retina. Following up on this clue, geneticists concentrated their attention on those genes that are highly expressed in the retina when screening other individuals with retinitis pigmentosa. This approach of using additional information to focus screening efforts on a subset of candidate genes led to identification of additional rare causative mutations in many different genes encoding retinal proteins.

A further complication in the genetic dissection of human diseases is posed by diabetes, heart disease, obesity, predisposition to cancer, and a variety of mental disorders that have at least some heritable properties. These and many other diseases can be considered to be *polygenic diseases* in the sense that alleles of multiple genes, acting together within an individual, contribute to both the occurrence and the severity of disease. How to systematically map complex polygenic traits in humans is one of the most important and challenging problems in human genetics today.

One of the most promising methods to study diseases that exhibit genetic heterogeneity or are polygenic is to seek a statistical correlation between inheritance of a particular region of a chromosome and the propensity to have a disease using a procedure known as a genome-wide association study (GWAS). The identification of disease-causing genes by GWAS relies on the phenomenon of linkage disequilibrium described previously. If an allele that causes or even predisposes an individual to a disease has occurred relatively recently during human evolution, the disease-causing allele will tend to remain associated with the particular set of DNA-based markers in the neighborhood of its chromosomal location. By examining a large number of DNA markers in populations of individuals with a particular disease as well as in control populations of individuals without the disease, chromosomal regions that tend to be correlated with occurrence of the disease can be identified with

GWAS. Genomic sequencing and other methods can then be used to identify possible disease causing mutations in these regions. Although GWAS can be a powerful tool to identify candidate disease genes, much further work is needed to determine how an individual carrying a particular mutation might be predisposed to the disease.

Models of human disease in experimental organisms may also contribute to unraveling the genetics of complex traits such as obesity or diabetes. For instance, large-scale controlled breeding experiments in mice can identify mouse genes associated with diseases analogous to those in humans. The human orthologs of the mouse genes identified in such studies would be likely candidates for involvement in the corresponding human disease. DNA from human populations then could be examined to determine if particular alleles of the candidate genes show a tendency to be present in individuals affected with the disease but absent from unaffected individuals. This “candidate gene” approach is currently being used intensively to search for genes that may contribute to the major polygenic diseases in humans.

KEY CONCEPTS of Section 5.4

Locating and Identifying Human Disease Genes

- Inherited diseases and other traits in humans show three major patterns of inheritance: autosomal dominant, autosomal recessive, and X-linked recessive (see Figure 5-35).
- Genes for human diseases and other traits can be mapped by determining their co-segregation during meiosis with markers whose locations in the genome are known. The closer a gene is to a particular marker, the more likely they are to co-segregate.
- Mapping of human genes with great precision requires thousands of molecular markers distributed along the chromosomes. The most useful markers are differences in the DNA sequence (polymorphisms) between individuals in noncoding regions of the genome.
- DNA polymorphisms useful in mapping human genes include single-nucleotide polymorphisms (SNPs) and simple sequence-repeats (SSRs).
- Linkage mapping often can locate a human disease gene to a chromosomal region that includes as many as 10 genes. To identify the gene of interest within this candidate region typically requires expression analysis and comparison of DNA sequences between wild-type and disease-affected individuals.
- Some inherited diseases can result from mutations in different genes in different individuals (genetic heterogeneity). The occurrence and severity of other diseases depend on the presence of mutant alleles of multiple genes in the same individuals (polygenic traits). Mapping of the genes associated with such diseases can be achieved by finding a statistical correlation between the disease and a particular chromosomal location in a genome-wide association study.

5.5 Inactivating the Function of Specific Genes in Eukaryotes

The elucidation of DNA and protein sequences in recent years has led to identification of many genes, using sequence patterns in genomic DNA and the sequence similarity of the encoded proteins with proteins of known function. As discussed in Chapter 6, the general functions of proteins identified by sequence searches may be predicted by analogy with known proteins. However, the precise *in vivo* roles of such “new” proteins may be unclear in the absence of mutant forms of the corresponding genes. In this section, we describe several ways for disrupting the normal function of a specific gene in the genome of an organism. Analysis of the resulting mutant phenotype often helps reveal the *in vivo* function of the normal gene and its encoded protein.

Three basic approaches underlie these gene-inactivation techniques: (1) replacing a normal gene with other sequences, (2) introducing an allele whose encoded protein inhibits functioning of the expressed normal protein, and (3) promoting destruction of the mRNA expressed from a gene. The normal endogenous gene is modified in techniques based on the first approach but is not modified in the other approaches.

Normal Yeast Genes Can Be Replaced with Mutant Alleles by Homologous Recombination

Modifying the genome of the yeast *S. cerevisiae* is particularly easy for two reasons: yeast cells readily take up exogenous DNA under certain conditions, and the introduced DNA is efficiently exchanged for the homologous chromosomal site in the recipient cell. This specific, targeted recombination of identical stretches of DNA allows any gene in yeast chromosomes to be replaced with a mutant allele. (As we discuss in Section 5.1, recombination between homologous chromosomes also occurs naturally during meiosis.)

In one popular method for disrupting yeast genes in this fashion, the PCR is used to generate a *disruption construct* containing a selectable marker that subsequently is transfected into yeast cells. As shown in Figure 5-39a, primers for PCR amplification of the selectable marker are designed to include about 20 nucleotides identical with sequences flanking the yeast gene to be replaced. The resulting amplified construct comprises the selectable marker (e.g., the *kanMX* gene, which like *neo^r* confers resistance to G-418) flanked by about 20 base pairs that match the ends of the target yeast gene. Transformed diploid yeast cells in which one of the two copies of the target endogenous gene has been replaced by the disruption construct are identified by their resistance to G-418 or other selectable phenotype. These heterozygous diploid yeast cells generally grow normally regardless of the function of the target gene, but half the haploid spores derived from these cells will carry only the disrupted allele (Figure 5-39b). If a gene is essential for viability, then spores carrying a disrupted allele will not survive.

EXPERIMENTAL FIGURE 5-39 Homologous recombination with transfected disruption constructs can inactivate specific target genes in yeast. (a) A suitable construct for disrupting a target gene can be prepared by the PCR. The two primers designed for this purpose each contain a sequence of about 20 nucleotides (nt) that is homologous to one end of the target yeast gene as well as sequences needed to amplify a segment of DNA carrying a selectable marker gene such as *kanMX*, which confers resistance to G-418. (b) When recipient diploid *Saccharomyces* cells are transformed with the gene-disruption construct, homologous recombination between the ends of the construct and the corresponding chromosomal sequences will integrate the *kanMX* gene into the chromosome, replacing the target gene sequence. The recombinant diploid cells will grow on a medium containing G-418, whereas nontransformed cells will not. If the target gene is essential for viability, half the haploid spores that form after sporulation of recombinant diploid cells will be nonviable.

Disruption of yeast genes by this method is proving particularly useful in assessing the role of proteins identified by analysis of the entire genomic DNA sequence (see Chapter 6). A large consortium of scientists has replaced each of the approximately 6000 genes identified by this analysis with the *kanMX* disruption construct and determined which gene disruptions lead to nonviable haploid spores. These analyses have shown that about 4500 of the 6000 yeast genes are not required for viability, an unexpectedly large number of apparently nonessential genes. In some cases, disruption of a particular gene may give rise to subtle defects that do not compromise the viability of yeast cells growing under laboratory conditions. Alternatively, cells carrying a disrupted gene may be viable because of operation of backup or compensatory pathways. To investigate this possibility, yeast geneticists currently are searching for synthetic lethal mutations that might reveal nonessential genes with redundant functions (see Figure 5-9c).

Transcription of Genes Ligated to a Regulated Promoter Can Be Controlled Experimentally

Although disruption of an essential gene required for cell growth will yield nonviable spores, this method provides little information about what the encoded protein actually does in cells. To learn more about how a specific gene contributes to cell growth and viability, investigators must be able to selectively inactivate the gene in a population of growing cells. One method for doing this employs a regulated promoter to selectively shut off transcription of an essential gene.

A useful promoter for this purpose is the yeast *GAL1* promoter, which is active in cells grown on galactose but completely inactive in cells grown on glucose. In this approach, the coding sequence of an essential gene (*X*) ligated to the *GAL1* promoter is inserted into a yeast shuttle vector (see Figure 5-17a). The recombinant vector then is introduced into haploid yeast cells in which gene *X* has been disrupted. Haploid cells that are transformed will grow on galactose medium since the normal copy of gene *X* on the vector is expressed in the presence of galactose. When the cells are transferred to a glucose-containing medium, gene *X* no longer is transcribed; as the cells divide, the amount of the encoded protein *X* will decline, eventually reaching a state of depletion that mimics a complete loss-of-function mutation. The observed changes in the phenotype of these cells after the shift to glucose medium may suggest which cell processes depend on the protein encoded by the essential gene *X*.

In an early application of this method, researchers explored the function of cytosolic *Hsc70* genes in yeast. Haploid cells with a disruption in all four redundant *Hsc70* genes were nonviable unless the cells carried a vector containing a copy of the *Hsc70* gene that could be expressed from the *GAL1* promoter on galactose medium. On transfer to glucose, the vector-carrying cells eventually stopped growing because of insufficient *Hsc70* activity. Careful examination of these dying cells revealed that their secretory proteins could no longer enter the endoplasmic reticulum (ER). This

study provided the first evidence for the unexpected role of *Hsc70* protein in translocation of secretory proteins into the ER, a process examined in detail in Chapter 13.

Specific Genes Can Be Permanently Inactivated in the Germ Line of Mice

Many of the methods for disrupting genes in yeast can be applied to genes of higher eukaryotes. These altered genes can be introduced into the germ line via homologous recombination to produce animals with a **gene knockout**, or simply “knockout.” Knockout mice in which a specific gene is disrupted are a powerful experimental system for studying mammalian development, behavior, and physiology. They also are useful in studying the molecular basis of certain human genetic diseases.

Gene-targeted knockout mice are generated by a two-stage procedure. In the first stage, a DNA construct containing a disrupted allele of a particular target gene is introduced into embryonic stem (ES) cells. These cells, which are derived from the blastocyst, can be grown in culture through many generations (see Figure 21-7). In a small fraction of transfected cells, the introduced DNA undergoes homologous recombination with the target gene, although recombination at nonhomologous chromosomal sites occurs much more frequently. To select for cells in which homologous gene-targeted insertion occurs, the recombinant DNA construct introduced into ES cells needs to include two selectable marker genes (Figure 5-40). One of these genes (*neo^r*), which confers G-418 resistance, is inserted within the target gene (*X*), thereby disrupting it. The other selectable gene, the thymidine kinase gene from herpes simplex virus (*tk^{HSV}*), is inserted into the construct outside the target-gene sequence. ES cells that undergo recombination between the DNA construct and the homologous site on the chromosome will contain *neo^r* but will not incorporate *tk^{HSV}*. Because *tk^{HSV}* confers sensitivity to the cytotoxic nucleotide analog ganciclovir, the desired recombinant ES cells can be selected by their ability to survive in the presence of both G-418 and ganciclovir. In these cells, one allele of gene *X* will be disrupted.

In the second stage in production of knockout mice, ES cells heterozygous for a knockout mutation in gene *X* are injected into a recipient wild-type mouse blastocyst, which subsequently is transferred into a surrogate pseudopregnant female mouse (Figure 5-41). The resulting progeny will be chimeras, containing tissues derived from both the transplanted ES cells and the host cells. If the ES cells also are homozygous for a visible marker trait (e.g., coat color), then chimeric progeny in which the ES cells survived and proliferated can be identified easily. Chimeric mice are then mated with mice homozygous for another allele of the marker trait to determine if the knockout mutation is incorporated into the germ line. Finally, mating of mice, each heterozygous for the knockout allele, will produce progeny homozygous for the knockout mutation.

EXPERIMENTAL FIGURE 5-40 Isolation of mouse ES cells with a gene-targeted disruption is the first stage in production of knockout mice.

(a) When exogenous DNA is introduced into embryonic stem (ES) cells, random insertion via nonhomologous recombination occurs much more frequently than gene-targeted insertion via homologous recombination. Recombinant cells in which one allele of gene *X* (orange and white) is disrupted can be obtained by using a recombinant vector that carries gene *X* disrupted with *neo^r* (green), which confers resistance to G-418, and, outside the region of homology, *tk^{HSV}* (yellow), the thymidine kinase gene from herpes simplex virus. The viral thymidine kinase, unlike the endogenous mouse enzyme, can convert the nucleotide analog ganciclovir into the monophosphate form; this is then modified to the triphosphate form, which inhibits cellular DNA replication in ES cells. Thus ganciclovir is cytotoxic for recombinant ES cells carrying the *tk^{HSV}* gene. Nonhomologous insertion includes the *tk^{HSV}* gene, whereas homologous insertion does not; therefore, only cells with nonhomologous insertion are sensitive to ganciclovir. (b) Recombinant cells are selected by treatment with G-418 since cells that fail to pick up DNA or integrate it into their genome are sensitive to this cytotoxic compound. The surviving recombinant cells are treated with ganciclovir. Only cells with a targeted disruption in gene *X*, and therefore lacking the *tk^{HSV}* gene and its accompanying cytotoxicity, will survive. [See S. L. Mansour et al., 1988, *Nature* 336:348.]

Development of knockout mice that mimic certain human diseases can be illustrated by cystic fibrosis. By methods discussed in Section 5.4, the recessive mutation that causes this disease eventually was shown to be located in a gene known as *CFTR*, which encodes a chloride channel. Using the cloned wild-type human *CFTR* gene, researchers isolated the homologous mouse gene and subsequently introduced mutations in it. The gene-knockout technique was then used to produce homozygous mutant mice, which showed symptoms (i.e., a phenotype), including disturbances to the functioning of epithelial cells, similar to those of humans with cystic fibrosis. These knockout mice are currently being used as a model system for studying this genetic disease and developing effective therapies. ■

Somatic Cell Recombination Can Inactivate Genes in Specific Tissues

Investigators often are interested in examining the effects of knockout mutations in a particular tissue of the mouse, at a specific stage in development, or both. However, mice carrying a germ-line knockout may have defects in numerous tissues or die before the developmental stage of interest. To address this problem, mouse geneticists have devised a clever technique to inactivate target genes in specific types of somatic cells or at particular times during development.

This technique employs site-specific DNA recombination sites (called *loxP sites*) and the enzyme Cre that catalyzes recombination between them. The *loxP-Cre recombination system* is derived from bacteriophage P1, but this site-specific recombination system also functions when placed in mouse

(a) Formation of ES cells carrying a knockout mutation

(b) Positive and negative selection of recombinant ES cells

cells. An essential feature of this technique is that expression of Cre is controlled by a cell-type-specific promoter. In *loxP-Cre* mice generated by the procedure depicted in Figure 5-42, inactivation of the gene of interest (*X*) occurs only in cells in which the promoter controlling the *cre* gene is active.

An early application of this technique provided strong evidence that a particular neurotransmitter receptor is important for learning and memory. Previous pharmacological and physiological studies had indicated that normal learning requires the NMDA class of glutamate receptors in the hippocampus, a region of the brain. But mice in which the gene

VIDEO: Microinjection of ES Cells into a Blastocyst

EXPERIMENTAL FIGURE 5-41 ES cells heterozygous for a disrupted gene are used to produce gene-targeted knockout mice.

Step 1: Embryonic stem (ES) cells heterozygous for a knockout mutation in a gene of interest (X) and homozygous for a dominant allele of a marker gene (here brown coat color, A) are transplanted into the blastocoel cavity of 4.5-day embryos that are homozygous for a recessive allele of the marker (here black coat color, a). Step 2: The early embryos then are implanted into a pseudopregnant female. Those progeny containing ES-derived cells are chimeras, indicated by their mixed black and brown coats. Step 3: Chimeric mice then are backcrossed to black mice; brown progeny from this mating have ES-derived cells in their germ line. Steps 4–6: Analysis of DNA isolated from a small amount of tail tissue can identify brown mice heterozygous for the knockout allele. Intercrossing of these mice produces some individuals homozygous for the disrupted allele, that is, knockout mice. [Adapted from M. R. Capecchi, 1989, *Trends Genet.* 5:70.]

encoding an NMDA receptor subunit was knocked out died neonatally, precluding analysis of the receptor's role in learning. Following the protocol in Figure 5-42, researchers generated mice in which the receptor subunit gene was inactivated in the hippocampus but expressed in other tissues. These mice survived to adulthood and showed learning and memory defects, confirming a role for these receptors in the ability of mice to encode their experiences into memory.

Dominant-Negative Alleles Can Functionally Inhibit Some Genes

In diploid organisms, as noted in Section 5.1, the phenotypic effect of a recessive allele is expressed only in homozygous individuals, whereas dominant alleles are expressed in heterozygotes. Thus an individual must carry two copies of a recessive allele but only one copy of a dominant allele to exhibit the corresponding phenotypes. We have seen how strains of mice that are homozygous for a given recessive knockout mutation can be produced by crossing individuals that are heterozygous for the same knockout mutation (see Figure 5-41). For experiments with cultured animal cells, however, it is usually difficult to disrupt both copies of a gene in order to produce a mutant phenotype. Moreover, the difficulty in producing strains with both copies of a gene mutated is often compounded by the presence of related genes of similar function that must also be inactivated in order to reveal an observable phenotype.

For certain genes, the difficulties in producing homozygous knockout mutants can be avoided by use of an allele carrying a dominant-negative mutation. These alleles are genetically dominant; that is, they produce a mutant phenotype even in cells carrying a wild-type copy of the gene. However, unlike other types of dominant alleles, dominant-negative alleles produce a phenotype equivalent to that of a loss-of-function mutation.

Useful dominant-negative alleles have been identified for a variety of genes and can be introduced into cultured cells by transfection or into the germ line of mice or other organisms. In both cases, the introduced gene is integrated into the genome by nonhomologous recombination. Such randomly inserted genes are called **transgenes**; the cells or

EXPERIMENTAL FIGURE 5-42 The loxP-Cre recombination system can knock out genes in specific cell types. A loxP site (purple) is inserted on each side of the essential exon 2 of the target gene X (blue) by homologous recombination, producing a loxP mouse. Since the loxP sites are in introns, they do not disrupt the function of X. The Cre mouse carries one gene X knockout allele and an introduced cre gene (orange) from bacteriophage P1 linked to a cell-type-specific promoter (yellow). The cre gene is incorporated into the mouse genome by nonhomologous recombination and does not affect the

function of other genes. In the loxP-Cre mice that result from crossing, Cre protein is produced only in those cells in which the promoter is active. Thus these are the only cells in which recombination between the loxP sites catalyzed by Cre occurs, leading to deletion of exon 2. Since the other allele is a constitutive gene X knockout, deletion between the loxP sites results in complete loss of function of gene X in all cells expressing Cre. By using different promoters, researchers can study the effects of knocking out gene X in various types of cells.

organisms carrying them are referred to as transgenic. Transgenes carrying a dominant-negative allele usually are engineered so that the allele is controlled by a regulated promoter, allowing expression of the mutant protein in different tissues at different times. As noted above, the random integration of exogenous DNA via nonhomologous recombination occurs at a much higher frequency than insertion via homologous recombination. Because of this phenomenon, the production of transgenic mice is an efficient and straight forward process (Figure 5-43).

Among the genes that can be functionally inactivated by introduction of a dominant-negative allele are those encoding small (monomeric) GTP-binding proteins belonging to the GTPase superfamily. As we will examine in several later chapters, these proteins (e.g., Ras, Rac, and Rab) act as intracellular switches. Conversion of the small GTPases from an inactive GDP-bound state to an active GTP-bound state depends on their interacting with a corresponding guanine nucleotide exchange factor (GEF). A mutant small GTPase that permanently binds to the GEF protein will block conversion of endogenous wild-type small GTPases to the active GTP-bound state, thereby inhibiting them from performing their switching function (Figure 5-44).

RNA Interference Causes Gene Inactivation by Destroying the Corresponding mRNA

The phenomenon known as **RNA interference (RNAi)** is perhaps the most straightforward method to inhibit the function of specific genes. This approach is technically simpler than the methods described above for disrupting genes. First observed in the roundworm *C. elegans*, RNAi refers to the ability of double-stranded RNA to block expression of its corresponding single-stranded mRNA but not that of mRNAs with a different sequence.

As described in Chapter 8, the phenomenon of RNAi rests on the general ability of eukaryotic cells to cleave double-stranded RNA into short (23-nt) double-stranded segments known as small inhibitory RNA (siRNA). The RNA endonuclease that catalyzes this reaction, known as Dicer, is found in all metazoans but not in simpler eukaryotes such as yeast. The siRNA molecules, in turn, can cause cleavage of mRNA molecules of matching sequence, in a reaction catalyzed by a protein complex known as RISC. RISC mediates recognition and hybridization between one strand of the siRNA and its complementary sequence on the target mRNA; subsequently, specific nucleases in the RISC complex

TECHNIQUE ANIMATION: Creating a Transgenic Mouse
VIDEO ANIMATION: DNA Injected into a Pronucleus of a Mouse Zygote

EXPERIMENTAL FIGURE 5-43 Transgenic mice are produced by random integration of a foreign gene into the mouse germ line.

Foreign DNA injected into one of the two pronuclei (the male and female haploid nuclei contributed by the parents) has a good chance of being randomly integrated into the chromosomes of the diploid zygote. Because a transgene is integrated into the recipient genome by nonhomologous recombination, it does not disrupt endogenous genes. [See R. L. Brinster et al., 1981, *Cell* 27:223.]

cleave the mRNA-siRNA hybrid. This model accounts for the specificity of RNAi, since it depends on base pairing, and for its potency in silencing gene function, since the complementary mRNA is permanently destroyed by nucleolytic degradation. The normal function of both Dicer and RISC is to allow for gene regulation by small endogenous RNA molecules known as micro-RNAs, or miRNAs.

Researchers exploit the micro-RNA pathway for intentional silencing of a gene of interest by using either of two general methods for generating siRNAs of defined sequence. In the first method, a double-stranded RNA corresponding to the target-gene sequence is produced by in vitro transcription of both sense and antisense copies of this sequence (Figure 5-45a).

(a) Cells expressing only wild-type alleles of a small GTPase

(b) Cells expressing both wild-type alleles and a dominant-negative allele

FIGURE 5-44 Inactivation of the function of a wild-type GTPase by the action of a dominant-negative mutant allele.

(a) Small (monomeric) GTPases (purple) are activated by their interaction with a guanine nucleotide exchange factor (GEF), which catalyzes the exchange of GDP for GTP. (b) Introduction of a dominant-negative allele of a small GTPase gene into cultured cells or transgenic animals leads to expression of a mutant GTPase that binds to and inactivates the GEF. As a result, endogenous wild-type copies of the same small GTPase are trapped in the inactive GDP-bound state. A single dominant-negative allele thus causes a loss-of-function phenotype in heterozygotes similar to that seen in homozygotes carrying two recessive loss-of-function alleles.

This dsRNA is injected into the gonad of an adult worm, where it is converted to siRNA by Dicer in the developing embryos. In conjunction with the RISC complex, the siRNA molecules cause the corresponding mRNA molecules to be destroyed rapidly. The resulting worms display a phenotype similar to the one that would result from disruption of the corresponding gene itself. In some cases, entry of just a few molecules of a particular dsRNA into a cell is sufficient to inactivate many copies of the corresponding mRNA. Figure 5-45b illustrates the ability of an injected dsRNA to interfere with production of the corresponding endogenous mRNA in *C. elegans* embryos. In this experiment, the mRNA levels in embryos were determined by in situ hybridization, as described earlier, using a fluorescently labeled probe.

The second method is to produce a specific double-stranded RNA in vivo. An efficient way to do this is to express a synthetic gene that is designed to contain tandem segments of both sense and antisense sequences corresponding to the

EXPERIMENTAL FIGURE 5-45 RNA interference (RNAi) can functionally inactivate genes in *C. elegans* and other organisms.

(a) In vitro production of double-stranded RNA (dsRNA) for RNAi of a specific target gene. The coding sequence of the gene, derived from either a cDNA clone or a segment of genomic DNA, is placed in two orientations in a plasmid vector adjacent to a strong promoter. Transcription of both constructs in vitro using RNA polymerase and ribonucleoside triphosphates yields many RNA copies in the sense orientation (identical with the mRNA sequence) or complementary antisense orientation. Under suitable conditions, these complementary RNA molecules will hybridize to form dsRNA. When the dsRNA is injected into cells, it is cleaved by Dicer into siRNAs. (b) Inhibition of *mex3* RNA expression in worm embryos by RNAi (see the text for the mechanism). (Left) Expression of *mex3* RNA in embryos was assayed by in situ hybridization with a probe specific for this mRNA, that is, linked to an enzyme that produces a colored (purple) product. (Right) The embryo derived from a worm injected with double-stranded *mex3* mRNA produces little or no endogenous *mex3* mRNA, as indicated by the absence of color. Each four-cell-stage embryo is $\approx 50 \mu\text{m}$ in length. (c) In vivo production of double-stranded RNA occurs via an engineered plasmid introduced directly into cells. The synthetic gene construct is a tandem arrangement of both sense and antisense sequences of the target gene. When it is transcribed, double-stranded small hairpin RNA forms (shRNA). The shRNA is cleaved by Dicer to form siRNA. [Part (b) from A. Fire et al., 1998, *Nature* 391:806.]

target gene (Figure 5-45c). When this gene is transcribed, a double-stranded RNA “hairpin” structure forms, known as *small hairpin RNA*, or shRNA. The shRNA will then be cleaved by Dicer to form siRNA molecules. The lentiviral expression vectors are particularly useful for introducing synthetic genes for the expression of shRNA constructs into animal cells.

Both RNAi methods lend themselves to systematic studies to inactivate each of the known genes in an organism and to observe what goes wrong. For example, in initial studies with *C. elegans*, RNA interference with 16,700 genes (about 86 percent of the genome) yielded 1722 visibly abnormal phenotypes. The genes whose functional inactivation causes particular abnormal phenotypes can be grouped into sets; each member of a set presumably controls the same signals or events. The regulatory relations between the genes in the set—for example, the genes that control muscle development—can then be worked out.

Other organisms in which RNAi-mediated gene inactivation has been successful include *Drosophila*, many kinds of plants, zebra fish, the frog *Xenopus*, and mice and are now the subjects of large-scale RNAi screens. For example, lentiviral vectors have been designed to inactivate by RNAi more than 10,000 different genes expressed in cultured mammalian cells. The function of the inactivated genes can be inferred from defects in growth or morphology of cell clones transfected with lentiviral vectors.

KEY CONCEPTS of Section 5.5

Inactivating the Function of Specific Genes in Eukaryotes

- Once a gene has been cloned, important clues about its normal function in vivo can be deduced from the observed phenotypic effects of mutating the gene.
- Genes can be disrupted in yeast by inserting a selectable marker gene into one allele of a wild-type gene via homologous recombination, producing a heterozygous mutant. When such a heterozygote is sporulated, disruption of an essential gene will produce two nonviable haploid spores (see Figure 5-39).
- A yeast gene can be inactivated in a controlled manner by using the *GAL1* promoter to shut off transcription of a gene when cells are transferred to glucose medium.

- In mice, modified genes can be incorporated into the germ line at their original genomic location by homologous recombination, producing knockouts (see Figures 5-40 and 5-41). Mouse knockouts can provide models for human genetic diseases such as cystic fibrosis.
- The *loxP*-Cre recombination system permits production of mice in which a gene is knocked out in a specific tissue.
- In the production of transgenic cells or organisms, exogenous DNA is integrated into the host genome by nonhomologous recombination (see Figure 5-43). Introduction of a dominant-negative allele in this way can functionally inactivate a gene without altering its sequence.
- In many organisms, including the roundworm *C. elegans*, double-stranded RNA triggers destruction of all the mRNA molecules with the same sequence (see Figure 5-45). This phenomenon, known as RNAi (RNA interference), provides a specific and potent means of functionally inactivating genes without altering their structure.

Perspectives for the Future

As the examples in this chapter and throughout the book illustrate, genetic analysis is the foundation of our understanding of many fundamental processes in cell biology. By examining the phenotypic consequences of mutations that inactivate a particular gene, geneticists are able to connect knowledge about the sequence, structure, and biochemical activity of the encoded protein to its function in the context of a living cell or multicellular organism. The classical approach to making these connections in both humans and simpler, experimentally accessible organisms has been to identify new mutations of interest based on their phenotypes and then to isolate the affected gene and its protein product.

Although scientists continue to use this classical genetic approach to dissect fundamental cellular processes and biochemical pathways, the availability of complete genomic sequence information for most of the common experimental organisms has fundamentally changed the way genetic experiments are conducted. Using various computational methods, scientists have identified the protein-coding gene sequences in most experimental organisms, including *E. coli*, yeast, *C. elegans*, *Drosophila*, *Arabidopsis*, mouse, and humans. The gene sequences, in turn, reveal the primary amino acid sequence of the encoded protein products, providing us with a nearly complete list of the proteins found in each of the major experimental organisms.

The approach taken by most researchers has thus shifted from discovering new genes and proteins to discovering the functions of genes and proteins whose sequences are already known. Once an interesting gene has been identified, genomic sequence information greatly speeds subsequent genetic manipulations of the gene, including its designed inactivation, so that more can be learned about its function.

Already sets of vectors for RNAi inactivation of most defined genes in the nematode *C. elegans* allow efficient genetic screens to be performed in this multicellular organism. These methods are now being applied to large collections of genes in cultured mammalian cells, and in the near future, either RNAi or knockout methods will have been used to inactivate every gene in the mouse.

In the past, a scientist might spend many years studying only a single gene, but nowadays scientists commonly study whole sets of genes at once. For example, with DNA microarrays the level of expression of all genes in an organism can be measured almost as easily as the expression of a single gene. One of the great challenges facing geneticists in the twenty-first century will be to exploit the vast amount of available data on the function and regulation of individual genes to understand how groups of genes are organized to form complex biochemical pathways and regulatory networks.

Review the Concepts

1. Genetic mutations can provide insights into the mechanisms of complex cellular or developmental processes. How might your analysis of a genetic mutation be different depending on whether a particular mutation is recessive or dominant?
2. What is a temperature-sensitive mutation? Why are temperature-sensitive mutations useful for uncovering the function of a gene?

3. Describe how complementation analysis can be used to reveal whether two mutations are in the same or in different genes. Explain why complementation analysis will not work with dominant mutations.

4. Jane has isolated a mutant strain of yeast that forms red colonies instead of the normal white when grown on a plate. To determine the mutant gene, she decides to use functional complementation with a DNA library containing a lysine selection marker. In addition to the unknown gene mutation, the yeast are lacking the gene required to synthesize the amino acids leucine and lysine. What media will Jane grow her yeast on to ensure that they have acquired the library plasmids? How will she know when a library plasmid has complemented her yeast mutation?

5. Restriction enzymes and DNA ligase play essential roles in DNA cloning. How is it that a bacterium that produces a restriction enzyme does not cut its own DNA? Describe some general features of restriction-enzyme sites. What are the three types of DNA ends that can be generated after cutting DNA with restriction enzymes? What reaction is catalyzed by DNA ligase?

6. Bacterial plasmids often serve as cloning vectors. Describe the essential features of a plasmid vector. What are the advantages and applications of plasmids as cloning vectors?

7. A DNA library is a collection of clones, each containing a different fragment of DNA, inserted into a cloning vector. What is the difference between a cDNA and a genomic DNA library? You would like to clone gene X, a gene expressed only in neurons, into a vector using a library as the source of insert. If you have the following libraries at your disposal (genomic library from skin cells, cDNA library from skin cells, genomic library from neurons, cDNA library from neurons), which could you use and why?

8. In 1993, Kary Mullis won the Nobel Prize in Chemistry for his invention of the PCR process. Describe the three steps in each cycle of a PCR reaction. Why was the discovery of a thermostable DNA polymerase (e.g., *Taq* polymerase) so important for the development of PCR?

9. Southern and Northern blotting are powerful tools in molecular biology based on hybridization of nucleic acids. How are these techniques the same? How do they differ? Give some specific applications for each blotting technique.

10. A number of foreign proteins have been expressed in bacterial and mammalian cells. Describe the essential features of a recombinant plasmid that are required for expression of a foreign gene. How can you modify the foreign protein to facilitate its purification? What is the advantage of expressing a protein in mammalian cells versus bacteria?

11. Northern blotting, RT-PCR, and microarrays can be used to analyze gene expression. A lab studies yeast cells, comparing their growth in two different sugars, glucose and galactose. One student is comparing expression of the gene *HMG2* under the different conditions. Which technique(s) could he use and why? Another student wants to compare expression of all the genes on chromosome 4, of which there are approximately 800. What technique(s) could she use and why?

12. In determining the identity of the protein that corresponds to a newly discovered gene, it often helps to know the pattern of tissue expression for that gene. For example, researchers have found that a gene called *SERPINA6* is expressed in the liver, kidney, and pancreas but not in other tissues. What techniques might researchers use to find out which tissues express a particular gene?

13. DNA polymorphisms can be used as DNA markers. Describe the differences between SNP and SSR polymorphisms. How can these markers be used for DNA-mapping studies?

14. How can linkage-disequilibrium mapping sometimes provide a much higher resolution of gene location than classical linkage mapping?

15. Genetic linkage studies can usually only roughly locate the chromosomal position of a "disease" gene. How can expression analysis and DNA sequence analysis help locate a disease gene within the region identified by linkage mapping?

16. The ability to selectively modify the genome in the mouse has revolutionized mouse genetics. Outline the procedure for generating a knockout mouse at a specific genetic locus. How can the *loxP*-Cre system be used to conditionally knock out a gene? What is an important medical application of knockout mice?

17. Two methods for functionally inactivating a gene without altering the gene sequence are by dominant-negative mutations and RNA interference (RNAi). Describe how each method can inhibit expression of a gene.

Analyze the Data

1. A culture of yeast that requires uracil for growth (*ura3*⁻) was mutagenized, and two mutant colonies, X and Y, have been isolated. Mating type α cells of mutant X are mated with mating type α cells of mutant Y to form diploid cells. The parental (*ura3*⁻), X, Y, and diploid cells are streaked onto agar plates containing uracil and incubated at 23 °C or 32 °C. Cell growth was monitored by the formation of colonies on the culture plates as shown in the figure below.

a. What can be deduced about mutants X and Y from the data provided?

b. A wild-type yeast cDNA library, prepared in a plasmid that contains the wild-type *URA3*⁺ gene, is used to transform X

cells, which are then cultured as indicated. Each black spot below represents a single clone growing on a petri plate. What are the molecular differences between the clones growing on the two plates? How can these results be used to identify the plasmid that contains a wild-type copy of gene X? Based on these results, how can the identity of gene X be uncovered?

Growth at 23 °C on media lacking uracil

Growth at 32 °C on media lacking uracil

c. DNA is extracted from the parental cells, from X cells, and from Y cells. PCR primers are used to amplify the gene encoding X in both the parental and the X cells. The primers are complementary to regions of DNA just external to the gene encoding X. The PCR results are shown in the gel at the right. What can be deduced about the mutation in the X gene from these data?

Parental X Y
Southern

Parental X
PCR

d. A construct of the wild-type gene X is engineered to encode a fusion protein in which green fluorescent protein (GFP) is present at the N-terminus (GFP-X) or the C-terminus (X-GFP) of protein X. Both constructs, present on a *URA3⁺* plasmid, are used to transform X cells grown in the absence of uracil. The transformants are then monitored for growth at 32 °C, shown below at the left. At the right are typical fluorescent images of X-GFP and GFP-X cells grown at 23 °C in which green denotes the presence of green fluorescent protein. What is a reasonable explanation for growth of GFP-X but not X-GFP cells at 32 °C?

Growth at 32 °C

GFP localization in cells grown at 23 °C

e. Haploid offspring of the diploid cells from part (a) above are generated. XY double mutants constitute 1/4 of these offspring. Haploid X cells, Y cells, and XY cells in liquid culture are synchronized at a stage just prior to budding and then are shifted from 23 °C to 32 °C. Examination of the cells 24 hours later reveals that X cells are arrested with small buds, Y cells are arrested with large buds, and XY cells are arrested with small buds. What is the relationship between X and Y?

Genes, Genomics, and Chromosomes

In previous chapters we learned how the structure and composition of proteins allow them to perform a wide variety of cellular functions. We also examined another vital component of cells, the nucleic acids, and the process by which information encoded in the sequence of DNA is translated into protein. In this chapter, our focus again is on DNA and proteins as we consider the characteristics of eukaryotic nuclear and organellar genomes: the features of genes and the other DNA sequence that comprise the genome, and how this DNA is structured and organized by proteins within the cell.

By the beginning of the twenty-first century, molecular biologists had completed sequencing the entire genomes of hundreds of viruses, scores of bacteria, and one unicellular eukaryote, the budding yeast *S. cerevisiae*. By now, the vast majority of the genome sequence is also known for the fission yeast *S. pombe*, the simple plant *A. thaliana*, rice, and multiple multicellular animals (metazoans) including the roundworm *C. elegans*, the fruit fly *D. melanogaster*, mice, humans and at least one representative each of the ≈ 35 metazoan phyla. Detailed analysis of these sequencing data has revealed insights into evolution, genome organization, and gene function. It has allowed researchers to identify previously unknown genes and to estimate the total number of protein-coding genes in each genome. Comparisons between

gene sequences often provide insight into possible functions of newly identified genes. Comparisons of genome sequence and organization between species also help us understand the evolution of organisms.

Surprisingly, DNA sequencing revealed that a large portion of the genomes of higher eukaryotes does not encode mRNAs or any other RNAs required by the organism. Remarkably, such noncoding DNA constitutes ≈ 98.5 percent of human chromosomal DNA! The noncoding DNA in multicellular organisms contains many regions that are similar but not identical. Variations within some stretches of this *repetitious DNA* between individuals are so great that every person can be distinguished by a DNA “fingerprint” based on these sequence variations. Moreover, some repetitious DNA sequences are not found in the same positions in the genomes of different individuals of the same species. At one time, all noncoding DNA was collectively termed “junk DNA” and was considered to serve no purpose. We now understand the evolutionary basis of all this extra DNA, and the variation in location of certain sequences between individuals. Cellular genomes harbor **transposable (mobile) DNA elements** that can copy themselves and move throughout the genome. Although transposable DNA elements seem to have little function in the life cycle of an individual organism, over evolutionary time they have shaped our genomes

and contributed to the rapid evolution of multicellular organisms.

In higher eukaryotes, DNA regions encoding proteins or functional RNAs—that is, **genes**—lie amidst this expanse of apparently nonfunctional DNA. In addition to the nonfunctional DNA *between* genes, noncoding **introns** are common *within* genes of multicellular plants and animals. Sequencing of the same protein-coding gene in a variety of eukaryotic species has shown that evolutionary pressure selects for maintenance of relatively similar sequences in the coding regions, or **exons**. In contrast, wide sequence variation, even including total loss, occurs among introns, suggesting that most intron sequences have little functional significance. However, as we shall see, although most of the DNA sequence of introns is not functional, the existence of introns has favored the evolution of multidomain proteins that are common in higher eukaryotes. It also allowed the rapid evolution of proteins with new combinations of functional domains. In addition, short noncoding RNAs called siRNAs and miRNAs that regulate translation and mRNA stability, and long noncoding RNAs that may regulate transcription through their influence on chromatin structure, can be processed from some introns (Chapters 7 and 8).

Mitochondria and chloroplasts also contain DNA that encodes proteins essential to the function of these vital organelles. We shall see that mitochondrial and chloroplast DNAs are evolutionary remnants of the origins of these organelles. Comparison of DNA sequences between different classes of bacteria and mitochondrial and chloroplast genomes

has revealed that these organelles evolved from intracellular eubacteria that developed symbiotic relationships with ancient eukaryotic cells.

The sheer length of cellular DNA is a significant problem with which cells must contend. The DNA in a single human cell, which measures about 2 meters in total length, must be contained within cells with diameters of less than 10 μm , a compaction ratio of greater than 10^5 to 1. In relative terms, if a cell were 1 centimeter in diameter (about the size of a pea), the length of DNA packed into its nucleus would be about 2 kilometers (1.2 miles)! Specialized eukaryotic proteins associated with nuclear DNA exquisitely fold and organize the DNA so that it fits into nuclei. And yet, at the same time, any given portion of this highly compacted DNA can be accessed readily for transcription, DNA replication, and repair of DNA damage without the long DNA molecules becoming tangled or broken. Furthermore, the integrity of DNA must be maintained during the process of cell division when it is partitioned into daughter cells. In eukaryotes, the complex of DNA and the proteins that organize it, called **chromatin**, can be visualized as individual **chromosomes** during mitosis. As we will see in this and the following chapter, the organization of DNA into chromatin allows a mechanism for regulation of gene expression that is not available in bacteria.

In the first five sections of this chapter, we provide an overview of the landscape of eukaryotic genes and genomes. First we discuss the structure of eukaryotic genes and the complexities that arise in higher organisms from the processing of

FIGURE 6-1 Overview of the structure of genes and chromosomes. DNA of higher eukaryotes consists of unique and repeated sequences. Only ≈ 1.5 percent of human DNA encodes proteins and functional RNAs and the regulatory sequences that control their expression; the remainder is merely spacer DNA between genes and introns within genes. Much of this DNA, ≈ 45 percent in humans, is derived from mobile DNA elements, genetic symbiotes that have contributed to the evolution of contemporary genomes. Each chromosome consists of a single, long molecule of DNA up to ≈ 280 Mb in humans, organized into increasing levels of condensation by the histone and nonhistone proteins with which it is intricately complexed. Much smaller DNA molecules are localized in mitochondria and chloroplasts.

Major Types of DNA Sequence

Single-copy genes	Simple-sequence DNA
Gene families	Transposable DNA elements
Tandemly repeated genes	Spacer DNA
Introns	

mRNA precursors into alternatively spliced mRNAs. Next we discuss the main classes of eukaryotic DNA, including the special properties of transposable DNA elements and how they shaped contemporary genomes. We then consider organelle DNA and how it differs from nuclear DNA. This background prepares us to discuss **genomics**, computer-based methods for analyzing and interpreting vast amounts of sequence data. The final two sections of the chapter address how DNA is physically organized in eukaryotic cells. We consider the packaging of DNA and **histone** proteins into compact complexes called **nucleosomes** that are the fundamental building blocks of chromatin, the large-scale structure of chromosomes, and the functional elements required for chromosome duplication and segregation. Figure 6-1 provides an overview of these interrelated subjects. The understanding of genes, genomics, and chromosomes gained in this chapter will prepare us to explore current knowledge about how the synthesis and concentration of each protein and functional RNA in a cell is regulated in the following two chapters.

6.1 Eukaryotic Gene Structure

In molecular terms, a gene commonly is defined as *the entire nucleic acid sequence that is necessary for the synthesis of a functional gene product (polypeptide or RNA)*. According to this definition, a gene includes more than the nucleotides encoding an amino acid sequence or a functional RNA, referred to as the *coding region*. A gene also includes all the DNA sequences required for synthesis of a particular RNA transcript, no matter where those sequences are located in relation to the coding region. For example, in eukaryotic genes, transcription-control regions known as **enhancers** can lie 50 kb or more from the coding region. As we learned in Chapter 4, other critical noncoding regions in eukaryotic genes include the promoter, as well as sequences that specify 3' cleavage and polyadenylation, known as *poly(A) sites*, and splicing of primary RNA transcripts, known as *splice sites* (see Figure 4-15). Mutations in these sequences, which control transcription initiation and RNA processing, affect the normal expression and function of RNAs, producing distinct phenotypes in mutant organisms. We examine these various control elements of genes in greater detail in Chapters 7 and 8.

Although most genes are transcribed into mRNAs, which encode proteins, some DNA sequences are transcribed into RNAs that do not encode proteins (e.g., tRNAs and rRNAs, described in Chapter 4, and miRNAs and siRNAs that regulate mRNA translation and stability, discussed in Chapter 8). Because the DNA that encodes tRNAs, rRNAs, miRNAs, and siRNAs can cause specific phenotypes when they are mutated, these DNA regions generally are referred to as tRNA, rRNA, miRNA, and siRNA *genes*, even though the final products of these genes are RNA molecules and not proteins.

In this section, we will examine the structure of genes in bacteria and eukaryotes and discuss how their respective gene structures influence gene expression and evolution.

Most Eukaryotic Genes Contain Introns and Produce mRNAs Encoding Single Proteins

As discussed in Chapter 4, many bacterial mRNAs (e.g., the mRNA encoded by the *trp* operon) include the coding region for several proteins that function together in a biological process. Such mRNAs are said to be *polycistronic*. (A *cistron* is a genetic unit encoding a single polypeptide.) In contrast, most eukaryotic mRNAs are *monocistronic*; that is, each mRNA molecule encodes a single protein. This difference between polycistronic and monocistronic mRNAs correlates with a fundamental difference in their translation.

Within a bacterial polycistronic mRNA, a ribosome-binding site is located near the start site for each of the protein-coding regions, or cistrons, in the mRNA. Translation initiation can begin at any of these multiple internal sites, producing multiple proteins (see Figure 4-13a). In most eukaryotic mRNAs, however, the 5'-cap structure directs ribosome binding, and translation begins at the closest AUG start codon (see Figure 4-13b). As a result, translation begins only at this site. In many cases, the primary transcripts of eukaryotic protein-coding genes are processed into a single type of mRNA, which is translated to give a single type of polypeptide (see Figure 4-15).

Unlike bacterial and yeast genes, which generally lack introns, most genes in multicellular animals and plants contain introns, which are removed during RNA processing in the nucleus before the fully processed mRNA is exported to the cytosol for translation. In many cases, the introns in a gene are considerably longer than the exons. The median intron length in human genes is 3.3 kb. Some, however, are much longer: the longest known human intron is 17,106 bp and lies within the *titin* gene, encoding a structural protein in muscle cells. In comparison, most human exons contain only 50–200 base pairs. The typical human gene encoding an average-size protein is $\approx 50,000$ bp long, but more than 95 percent of that sequence consists of introns and flanking noncoding 5' and 3' regions.

Many large proteins in higher organisms that have repeated domains are encoded by genes consisting of repeats of similar exons separated by introns of variable length. An example of this is fibronectin, a component of the extracellular matrix. The fibronectin gene contains multiple copies of five types of exons (see Figure 4-16). Such genes evolved by tandem duplication of the DNA encoding the repeated exon, probably by unequal crossing over during meiosis as shown in Figure 6-2a.

Simple and Complex Transcription Units Are Found in Eukaryotic Genomes

The cluster of genes that forms a bacterial operon comprises a single **transcription unit** that is transcribed from a specific promoter in the DNA sequence to a termination site, producing a single primary transcript. In other words, genes and transcription units often are distinguishable in prokaryotes, since a single transcription unit contains several genes when they are part of an operon. In contrast, most eukaryotic genes

(a) Exon duplication

(b) Gene duplication

FIGURE 6-2 Exon and Gene Duplication. (a) Exon duplication results from unequal crossing over during meiosis. Each parental chromosome (top) contains one ancestral gene containing three exons and two introns. Homologous noncoding L1 repeated sequences lie 5' and 3' of the gene, and also in the intron between exons 2 and 3. As we shall see later in the chapter, L1 sequences have been repeatedly transposed to new sites in the genome over the course of human evolution, so that all chromosomes are peppered with them. The parental chromosomes are shown displaced relative to each other, so that the L1 sequences are aligned. Homologous recombination between L1 sequences as shown would

generate one recombinant chromosome where the gene now has four exons (two copies of exon 3) and one chromosome where the gene is missing exon 3. (b) The same process can generate duplications of entire genes. Each parental chromosome (top) contains one ancestral β -globin gene. After the unequal recombination between L1 sequences, subsequent independent mutations in the resulting duplicated genes could lead to slight changes in sequence that might result in slightly different functional properties of the encoded proteins. Unequal crossing over also can result from rare recombinations between unrelated sequences. [Part (b) see D. H. A. Fitch et al., 1991, *Proc. Nat'l Acad. Sci. USA* **88**:7396.]

are expressed from separate transcription units, and each mRNA is translated into a single protein.

Eukaryotic transcription units, however, are classified into two types, depending on the fate of the primary transcript. The primary transcript produced from a *simple* transcription unit, such as the one encoding β -globin (Figure 4-15), is processed to yield a single type of mRNA, encoding a single protein. Mutations in exons, introns, and transcription-control regions all may influence expression of the protein encoded by a simple transcription unit (Figure 6-3a). In humans, simple transcription units such as β -globin are rare. Approximately 90 percent of human transcription units are *complex*. The primary RNA transcript can be processed in more than one way, leading to formation of mRNAs containing different exons. Each alternate mRNA, however, is monocistronic, being translated into a single polypeptide, with translation usually initiating at the first AUG in the

mRNA. Multiple mRNAs can arise from a primary transcript in three ways, as shown in Figure 6-3b.

Examples of all three types of alternative RNA processing occur in the genes that regulate sexual differentiation in *Drosophila* (see Figure 8-16). Commonly, one mRNA is produced from a complex transcription unit in some cell types, and a different mRNA is made in other cell types. For example, **alternative splicing** of the primary fibronectin transcript in fibroblasts and hepatocytes determines whether or not the secreted protein includes domains that adhere to cell surfaces (see Figure 4-16). The phenomenon of alternative splicing greatly expands the number of proteins encoded in the genomes of higher organisms. It is estimated that ≈ 90 percent of human genes are contained within complex transcription units that give rise to alternatively spliced mRNAs encoding proteins with distinct functions, as for the fibroblast and hepatocyte forms of fibronectin.

(a) Simple transcription unit

(b) Complex transcription units

The relationship between a mutation and a gene is not always straightforward when it comes to complex transcription units. A mutation in the control region or in an exon shared by alternatively spliced mRNAs will affect all the alternative proteins encoded by a given complex transcription unit. On the other hand, mutations in an exon present in only one of the alternative mRNAs will affect only the protein encoded by that mRNA. As explained in Chapter 5, **genetic complementation** tests commonly are used to determine if two mutations are in the same or different genes (see Figure 5-7). However, in the complex transcription unit shown in Figure 6-3b (*middle*), mutations *d* and *e* would comple-

FIGURE 6-3 Simple and complex eukaryotic transcription units.

(a) A simple transcription unit includes a region that encodes one protein, extending from the 5' cap site to the 3' poly(A) site, and associated control regions. Introns lie between exons (light blue rectangles) and are removed during processing of the primary transcripts (dashed red lines); thus they do not occur in the functional monocistronic mRNA. Mutations in a transcription-control region (*a*, *b*) may reduce or prevent transcription, thus reducing or eliminating synthesis of the encoded protein. A mutation within an exon (*c*) may result in an abnormal protein with diminished activity. A mutation within an intron (*d*) that introduces a new splice site results in an abnormally spliced mRNA encoding a nonfunctional protein. (b) Complex transcription units produce primary transcripts that can be processed in alternative ways. (*Top*) If a primary transcript contains alternative splice sites, it can be processed into mRNAs with the same 5' and 3' exons but different internal exons. (*Middle*) If a primary transcript has two poly(A) sites, it can be processed into mRNAs with alternative 3' exons. (*Bottom*) If alternative promoters (*f* or *g*) are active in different cell types, mRNA₁, produced in a cell type in which *f* is activated, has a different first exon (1A) than mRNA₂ has, which is produced in a cell type in which *g* is activated (and where exon 1B is used). Mutations in control regions (*a* and *b*) and those designated *c* within exons shared by the alternative mRNAs affect the proteins encoded by both alternatively processed mRNAs. In contrast, mutations (designated *d* and *e*) within exons unique to one of the alternatively processed mRNAs affect only the protein translated from that mRNA. For genes that are transcribed from different promoters in different cell types (*bottom*), mutations in different control regions (*f* and *g*) affect expression only in the cell type in which that control region is active.

ment each other in a genetic complementation test, even though they occur in the same gene. This is because a chromosome with mutation *d* can express a normal protein encoded by mRNA₂ and a chromosome with mutation *e* can express a normal protein encoded by mRNA₁. Both mRNAs produced from this gene would be present in a diploid cell carrying both mutations, generating both protein products and hence a wild-type phenotype. However, a chromosome with mutation *c* in an exon common to both mRNAs would not complement either mutation *d* or *e*. In other words, mutation *c* would be in the same complementation groups as mutations *d* and *e*, even though *d* and *e* themselves would not be in the same complementation group! Given these complications with the genetic definition of a gene, the genomic definition outlined at the beginning of this section is commonly used. In the case of protein-coding genes, a gene is the DNA sequence transcribed into a pre-mRNA precursor, equivalent to a transcription unit, plus any other regulatory elements required for synthesis of the primary transcript. The various proteins encoded by the alternatively spliced mRNAs expressed from one gene are called **isoforms**.

Protein-Coding Genes May Be Solitary or Belong to a Gene Family

The nucleotide sequences within chromosomal DNA can be classified on the basis of structure and function, as shown in Table 6-1. We will examine the properties of each class, beginning with protein-coding genes, which comprise two groups.

TABLE 6-1 Major Classes of Nuclear Eukaryotic DNA and Their Representation in the Human Genome

Class	Length	Copy Number in Human Genome	Fraction of Human Genome (%)
Protein-coding genes	0.5–2200 kb	≈25,000	≈55* (11.8) [†]
Tandemly repeated genes			
U2 snRNA	6.1 kb [‡]	≈20	<0.001
rRNAs	43 kb [‡]	≈300	0.4
Repetitious DNA			
Simple-sequence DNA	1–500 bp	Variable	≈6
Interspersed repeats (mobile DNA elements)			
DNA transposons	2–3 kb	300,000	3
LTR retrotransposons	6–11 kb	440,000	8
Non-LTR retrotransposons			
LINEs	6–8 kb	860,000	21
SINEs	100–400bp	1,600,000	13
Processed pseudogenes	Variable	1–≈100	≈0.4
Unclassified spacer DNA [§]	Variable	n.a.	≈25

*Complete transcription units including introns.

[†]Transcription units not including introns. Protein-coding regions (exons) total 1.1% of the genome.

[‡]Length of each repeat in a tandemly repeated sequence.

[§]Sequences between transcription units that are not repeated in the genome; n.a. = not applicable.

SOURCE: International Human Genome Sequencing Consortium, 2001, *Nature* 409:860 and 2004, *Nature* 431:931.

In multicellular organisms, roughly 25–50 percent of the protein-coding genes are represented only once in the haploid genome and thus are termed *solitary* genes. A well-studied example of a solitary protein-coding gene is the chicken lysozyme gene. The 15-kb DNA sequence encoding chicken lysozyme constitutes a simple transcription unit containing four exons and three introns. The flanking regions, extending for about 20 kb upstream and downstream from the transcription unit, do not encode any detectable mRNAs. Lysozyme, an enzyme that cleaves the polysaccharides in bacterial cell walls, is an abundant component of chicken egg-white protein and also is found in human tears. Its activity helps to keep the surface of the eye and the chicken egg sterile.

Duplicated genes constitute the second group of protein-coding genes. These are genes with close but nonidentical sequences that often are located within 5–50 kb of one another. A set of duplicated genes that encodes proteins with similar but nonidentical amino acid sequences is called a **gene family**; the encoded, closely related, homologous proteins constitute a **protein family**. A few protein families, such as protein kinases, vertebrate immunoglobulins, and olfactory receptors, include hundreds of members. Most protein families, however, include from just a few to 30 or so members; common examples are cytoskeletal proteins, the myosin heavy chain, and the α - and β -globins in vertebrates.

The genes encoding the β -like globins are a good example of a gene family. As shown in Figure 6-4a, the β -like globin gene family contains five functional genes designated β , δ , A_γ , G_γ , and ϵ ; the encoded polypeptides are similarly designated. Two identical β -like globin polypeptides combine with two

identical α -globin polypeptides (encoded by another gene family) and four small heme groups to form a hemoglobin molecule (see Figure 3-13). All the hemoglobins formed from the different β -like globins carry oxygen in the blood, but they exhibit somewhat different properties that are suited to their specific functions in human physiology. For example, hemoglobins containing either the A_γ or G_γ polypeptides are expressed only during fetal life. Because these fetal hemoglobins have a higher affinity for oxygen than adult hemoglobins, they can effectively extract oxygen from the maternal circulation in the placenta. The lower oxygen affinity of adult hemoglobins, which are expressed after birth, permits better release of oxygen to the tissues, especially muscles, which have a high demand for oxygen during exercise.

The different β -globin genes arose by duplication of an ancestral gene, most likely as the result of an “unequal cross-over” during meiotic recombination in a developing germ cell (egg or sperm, see Figure 6-2b). Over evolutionary time the two copies of the gene that resulted accumulated random mutations; beneficial mutations that conferred some refinement in the basic oxygen-carrying function of hemoglobin were retained by natural selection, resulting in *sequence drift*. Repeated gene duplications and subsequent sequence drift are thought to have generated the contemporary globin-like genes observed in humans and other mammals today.

Two regions in the human β -like globin gene cluster contain nonfunctional sequences, called **pseudogenes**, similar to those of the functional β -like globin genes (see Figure 6-4a). Sequence analysis shows that these pseudogenes have the same apparent exon–intron structure as the functional β -like globin

(a) Human β -globin gene cluster (chromosome 11)

(b) *S. cerevisiae* (chromosome III)

FIGURE 6-4 Comparison of gene density in higher and lower eukaryotes. (a) In the diagram of the β -globin gene cluster on human chromosome 11, the green boxes represent exons of β -globin-related genes. Exons spliced together to form one mRNA are connected by caret-like spikes. The human β -globin gene cluster contains two pseudogenes (white); these regions are related to the functional globin-type genes but are not transcribed. Each red arrow indicates the location of an *Alu* sequence, an ≈ 300 -bp noncoding

repeated sequence that is abundant in the human genome. (b) In the diagram of yeast DNA from chromosome III, the green boxes indicate open reading frames. Most of these potential protein-coding sequences are functional genes without introns. Note the much higher proportion of noncoding-to-coding sequences in the human DNA than in the yeast DNA. [Part (a), see F. S. Collins and S. M. Weissman, 1984, *Prog. Nucl. Acid Res. Mol. Biol.* **31**:315. Part (b), see S. G. Oliver et al., 1992, *Nature* **357**:28.]

genes, suggesting that they also arose by duplication of the same ancestral gene. However, there was little selective pressure to maintain the function of these genes. Consequently, sequence drift during evolution generated sequences that either terminate translation or block mRNA processing, rendering such regions nonfunctional. Because such pseudogenes are not deleterious, they remain in the genome and mark the location of a gene duplication that occurred in one of our ancestors.

Duplications of segments of a chromosome (called *segmental duplication*) occurred fairly often during the evolution of multicellular plants and animals. As a result, a large fraction of the genes in these organisms today has been duplicated, allowing the process of sequence drift to generate gene families and pseudogenes. The extent of sequence divergence between duplicated copies of the genome and characterization of the homologous genome sequences in related organisms allows an estimate of the time in evolutionary history when the duplication occurred. For example, the human fetal γ -globin genes (G_γ and A_γ) evolved following the duplication of a 5.5-kb region in the β -globin locus that included the single γ -globin gene in the common ancestor of catarrhine primates (Old World monkeys, apes, and humans) and platyrrhine primates (New World monkeys) about 50 million years ago.

Although members of gene families that arose relatively recently in evolution, such as genes of the human β -globin locus, are often found near each other on the same chromosome, members of gene families may also be found on different chromosomes in the same organism. This is the case for the human α -globin genes, which were separated from the β -globin genes by an ancient chromosomal translocation. Both the α - and β -globin genes evolved from a single ancestral globin gene that was duplicated (see Figure 6-2b) to generate the predecessors of the contemporary α - and β -globin genes in mammals. Both the primordial α - and β -globin genes then underwent further duplications to generate the different

genes of the α - and β -globin gene clusters found in mammals today.

Several different gene families encode the various proteins that make up the cytoskeleton. These proteins are present in varying amounts in almost all cells. In vertebrates, the major cytoskeletal proteins are the actins, tubulins, and intermediate filament proteins such as the keratins, discussed in Chapters 17, 18, and 20. We examine the origin of one such family, the tubulin family, in Section 6.5. Although the physiological rationale for the cytoskeletal protein families is not as obvious as it is for the globins, the different members of a family probably have similar but subtly different functions suited to the particular type of cell in which they are expressed.

Heavily Used Gene Products Are Encoded by Multiple Copies of Genes

In vertebrates and invertebrates, the genes encoding ribosomal RNAs and some other nonprotein-coding RNAs such as those involved in RNA splicing occur as *tandemly repeated arrays*. These are distinguished from the duplicated genes of gene families in that the multiple tandemly repeated genes encode identical or nearly identical proteins or functional RNAs. Most often, copies of a sequence appear one after the other, in a head-to-tail fashion, over a long stretch of DNA. Within a tandem array of rRNA genes, each copy is nearly exactly like all the others. Although the transcribed portions of rRNA genes are the same in a given individual, the nontranscribed spacer regions between the transcribed regions can vary.

These tandemly repeated RNA genes are needed to meet the great cellular demand for their transcripts. To understand why, consider that a fixed maximal number of RNA copies can be produced from a single gene during one cell generation when the gene is fully loaded with RNA polymerase molecules. If more RNA is required than can be transcribed from

one gene, multiple copies of the gene are necessary. For example, during early embryonic development in humans, many embryonic cells have a doubling time of ≈ 24 hours and contain 5–10 million ribosomes. To produce enough rRNA to form this many ribosomes, an embryonic human cell needs at least 100 copies of the large and small subunit rRNA genes, and most of these must be close to maximally active for the cell to divide every 24 hours. That is, multiple RNA polymerases must be transcribing each rRNA gene at the same time (see Figure 8-36). Indeed, all eukaryotes, including yeasts, contain 100 or more copies of the genes encoding 5S rRNA and the large and small subunit rRNAs.

Multiple copies of tRNA genes and the genes encoding the histone proteins also occur. As we will see later in this chapter, histones bind and organize nuclear DNA. Just as the cell requires multiple rRNA and tRNA genes to support efficient translation, multiple copies of the histone genes are required to produce sufficient histone protein to bind the large amount of nuclear DNA produced in each round of replication. While tRNA and histone genes often occur in clusters, they generally do not occur in tandem arrays in the human genome.

Nonprotein-Coding Genes Encode Functional RNAs

In addition to rRNA and tRNA genes, there are hundreds of additional genes that are transcribed into nonprotein-coding RNAs, some with various known functions, and many whose functions are not yet known. For example, **small nuclear RNAs (snRNAs)** function in RNA splicing, and **small nucleolar RNAs (snoRNAs)** function in rRNA processing and base modification in the nucleolus. The RNase P RNA functions in tRNA processing, and a large family (≈ 1000) of short **micro RNAs (miRNAs)** regulates the translation and stability of specific mRNAs. The functions of these nonprotein-coding RNAs are discussed in Chapter 8. An RNA found in telomerase (see Figure 6-47) functions in maintaining the sequence at the ends of chromosomes, and the 7SL RNA functions in the import of secreted proteins and most membrane proteins into the endoplasmic reticulum (Chapter 13). These and other nonprotein-coding RNAs encoded in the human genome and their functions, when known, are listed in Table 6-2.

TABLE 6-2 Known Nonprotein-Coding RNAs and Their Functions

RNA	Number of Genes in Human Genome	Function
rRNAs	≈ 300	Protein synthesis
tRNAs	≈ 500	Protein synthesis
snRNAs	≈ 80	mRNA splicing
U7 snRNA	1	Histone mRNA 3' processing
snoRNAs	≈ 85	Pre-rRNA processing and rRNA modification
miRNAs	≈ 1000	Regulation of gene expression
Xist	1	X-chromosome inactivation
7SK	1	Transcription control
RNase P RNA	1	tRNA 5' processing
7SL RNA	3	Protein secretion (component of signal recognition particle, SRP)
RNase MRP RNA	1	rRNA processing
Telomerase RNA	1	Template for addition of telomeres
Vault RNAs	3	Components of Vault ribonucleoproteins (RNPs), function unknown
hY1, hY3, hY4, hY 5	≈ 30	Components of ribonucleoproteins (RNPs), function unknown
H19	1	Unknown

KEY CONCEPTS of Section 6.1

Eukaryotic Gene Structure

- In molecular terms, a gene is the entire DNA sequence required for synthesis of a functional protein or RNA molecule. In addition to the coding regions (exons), a gene includes control regions and sometimes introns.
- A simple eukaryotic transcription unit produces a single monocistronic mRNA, which is translated into a single protein.
- A complex eukaryotic transcription unit is transcribed into a primary transcript that can be processed into two or more different monocistronic mRNAs depending on the choice of splice sites or polyadenylation sites. A complex transcription unit with alternate promoters or alternate polyadenylation sites also generates two or more different mRNAs (see Figure 6-3b).
- Many complex transcription units (e.g., the fibronectin gene) express one mRNA in one cell type and an alternate mRNA in a different cell type.
- About half the protein-coding genes in vertebrate genomic DNA are solitary genes, each occurring only once in the haploid genome. The remainder are duplicated genes, which arose by duplication of an ancestral gene and subsequent independent mutations (see Figure 6-2b). The proteins encoded by a gene family have homologous but nonidentical amino acid sequences and exhibit similar but slightly different properties.
- In invertebrates and vertebrates, rRNAs are encoded by multiple copies of genes located in tandem arrays in genomic DNA. Multiple copies of tRNA and histone genes also occur, often in clusters, but not generally in tandem arrays.
- Many genes also encode functional RNAs that are not translated into protein but nonetheless perform significant functions, such as rRNA, tRNA, and snRNAs. Among these are micro RNAs; possibly up to 1000 in humans, whose biological significance in regulating gene expression has only recently been appreciated.

6.2 Chromosomal Organization of Genes and Noncoding DNA

Having reviewed the relationship between transcription units and genes, we now consider the organization of genes on chromosomes and the relationship of noncoding DNA sequences to coding sequences.

Genomes of Many Organisms Contain Nonfunctional DNA

Comparisons of the total chromosomal DNA per cell in various species first suggested that much of the DNA in certain organisms does not encode RNA or have any apparent regu-

latory function. For example, yeasts, fruit flies, chickens, and humans have successively more DNA in their haploid chromosome sets (12; 180; 1300; and 3300 Mb, respectively), in keeping with what we perceive to be the increasing complexity of these organisms. Yet the vertebrates with the greatest amount of DNA per cell are amphibians, which are surely less complex than humans in their structure and behavior. Even more surprising, the unicellular protozoan species *Amoeba dubia* has 200 times more DNA per cell than humans. Many plant species also have considerably more DNA per cell than humans have. For example, tulips have 10 times as much DNA per cell as humans. The DNA content per cell also varies considerably between closely related species. All insects or all amphibians would appear to be similarly complex, but the amount of haploid DNA in species within each of these phylogenetic classes varies by a factor of 100.

Detailed sequencing and identification of exons in chromosomal DNA have provided direct evidence that the genomes of higher eukaryotes contain large amounts of noncoding DNA. For instance, only a small portion of the β -globin gene cluster of humans, about 80 kb long, encodes protein (see Figure 6-4a). In contrast, a typical 80-kb stretch of DNA from the yeast *S. cerevisiae*, a single-celled eukaryote, contains many closely spaced protein-coding sequences without introns and relatively much less noncoding DNA (see Figure 6-4b). Moreover, compared with other regions of vertebrate DNA, the β -globin gene cluster is unusually rich in protein-coding sequences, and the introns in globin genes are considerably shorter than those in most human genes. Globin proteins comprise >50 percent of the total protein in developing red blood cells (reticulocytes) and the globin genes are expressed at maximum rate, i.e., a new RNA polymerase initiates transcription as soon as the previous polymerase transcribes far enough from the promoter to allow a second RNA polymerase to bind and initiate. Consequently, there has been selective pressure to evolve small introns in the globin genes that are compatible with the required high rate of globin mRNA transcription and processing. However, the vast majority of human genes are expressed at much lower levels requiring production of one encoded mRNA on a time scale of only tens of minutes or hours. Consequently, there has been little selective pressure to reduce the sizes of introns in most human genes.

The density of genes varies greatly in different regions of human chromosomal DNA, from “gene-rich” regions, such as the β -globin cluster, to large gene-poor “gene deserts.” Of the 96 percent of human genomic DNA that has been sequenced, only ≈ 1.5 percent corresponds to protein-coding sequences (exons). We learned in the previous section that the intron sequences of most human genes are significantly longer than the exon sequences. Approximately one-third of human genomic DNA is thought to be transcribed into pre-mRNA precursors or nonprotein-coding RNAs in one cell or another, but some 95 percent of this sequence is intronic, and thus removed by RNA splicing. This amounts to a large fraction of the total genome. The remaining two-thirds of human DNA is noncoding DNA between genes as well as

regions of repeated DNA sequences that make up the centromeres and telomeres of the human chromosomes. Consequently, ≈ 98.5 percent of human DNA is noncoding.

Different selective pressures during evolution may account, at least in part, for the remarkable difference in the amount of nonfunctional DNA in different organisms. For example, many microorganisms must compete with other species of microorganisms in the same environment for limited amounts of available nutrients, and metabolic economy thus is a critical characteristic. Since synthesis of nonfunctional (i.e., noncoding) DNA requires time, nutrients, and energy, presumably there was selective pressure to lose nonfunctional DNA during the evolution of many rapidly growing microorganisms such as the yeast *S. cerevisiae*. On the other hand, natural selection in vertebrates depends largely on their behavior. The energy invested in DNA synthesis is trivial compared with the metabolic energy required for the movement of muscles; thus there may have been little selective pressure to eliminate nonfunctional DNA in vertebrates. Also, the replication time of cells in most multicellular organisms is much longer than in rapidly growing microorganisms, so there was little selective pressure to eliminate nonfunctional DNA in order to permit rapid cellular replication.

Most Simple-Sequence DNAs Are Concentrated in Specific Chromosomal Locations

Besides duplicated protein-coding genes and tandemly repeated genes, eukaryotic cells contain multiple copies of other DNA sequences in the genome, generally referred to as repetitious DNA (see Table 6-1). Of the two main types of repetitious DNA, the less prevalent is **simple-sequence DNA** or **satellite DNA**, which constitutes about 6 percent of the human genome and is composed of perfect or nearly perfect repeats of relatively short sequences. The more common type of repetitious DNA, collectively called **interspersed repeats**, is composed of much longer sequences. These sequences, consisting of several types of transposable elements, are discussed in Section 6.3.

The length of each repeat in simple-sequence DNA can range from 1 to 500 base pairs. Simple-sequence DNAs in which the repeats contain 1–13 base pairs are often called **microsatellites**. Most microsatellite DNA has a repeat length of 1–4 base pairs and usually occurs in tandem repeats of 150 repeats or fewer. Microsatellites are thought to have originated by “backward slippage” of a daughter strand on its template strand during DNA replication so that the same short sequence is copied twice (Figure 6-5).

 Microsatellites occasionally occur within transcription units. Some individuals are born with a larger number of repeats in specific genes than are observed in the general population, presumably because of daughter-strand slippage during DNA replication in a germ cell from which they developed. Such expanded microsatellites have been found to cause at least 14 different types of neuromuscular diseases, depending on the gene in which they occur. In some cases expanded microsatellites behave like a recessive mutation because they interfere

with just the function or expression of the encoded gene. But in the more common types of diseases associated with expanded microsatellite repeats, such as *Huntington disease* and *myotonic dystrophy type 1*, the expanded repeats behave like dominant mutations. In some microsatellite-repeat diseases, triplet repeats occur within a coding region, resulting in the formation of long polymers of a single amino acid that may aggregate over time in long-lived neuronal cells, eventually interfering with normal cellular function. For example, expansion of a CAG repeat in the first exon of the Huntington gene leads to synthesis of long stretches of polyglutamine that over several decades form toxic aggregates resulting in neuronal cell death in Huntington disease.

Pathogenic expanded repeats can also occur in the noncoding regions of some genes, where they are thought to

FIGURE 6-5 Generation of microsatellite repeats by backward slippage of the nascent daughter strand during DNA replication. If, during replication (a), the nascent daughter strand “slips” backward relative to the template strand by one repeat, one new copy of the repeat is added to the daughter strand when DNA replication continues (b). An extra copy of the repeat forms a single-stranded loop in the daughter strand of the daughter duplex DNA molecule. If this single-stranded loop is not removed by DNA repair proteins before the next round of DNA replication (c), the extra copy of the repeat is added to one of the double-stranded daughter DNA molecules.

function as dominant mutations because they interfere with RNA processing of a subset of mRNAs in the muscle cells and neurons where the affected genes are expressed. For example, in patients with myotonic dystrophy type 1, transcripts of the *DMPK* gene contain between 50 and 1500 repeats of the sequence CUG in the 3' untranslated region, compared to 5 to 34 repeats in normal individuals. The extended stretch of CUG repeats in affected individuals is thought to form long RNA hairpins (see Figure 4-9), which bind and sequester nuclear RNA-binding proteins that normally regulate alternative RNA splicing of a subset of pre-mRNAs essential for muscle and nerve cell function. ■

Most simple-sequence satellite DNA is composed of repeats of 14–500 base pairs in tandem arrays of 20–100 kb. In situ hybridization studies with metaphase chromosomes have localized these simple-sequence DNAs to specific chromosomal regions. Much of this DNA lies near centromeres, the discrete chromosomal regions that attach to spindle microtubules during mitosis and meiosis (Figure 6-6). Experiments in the fission yeast *Schizosaccharomyces pombe* indicate that these sequences are required to form a specialized chromatin structure called *centromeric heterochromatin*, necessary for

EXPERIMENTAL FIGURE 6-6 Simple-sequence DNA is localized at the centromere in mouse chromosomes. Purified simple-sequence DNA from mouse cells was copied in vitro using *E. coli* DNA polymerase I and fluorescently labeled dNTPs to generate a fluorescently labeled DNA “probe” for mouse simple-sequence DNA. Chromosomes from cultured mouse cells were fixed and denatured on a microscope slide, and then the chromosomal DNA was hybridized in situ to the labeled probe (light blue). The slide was also stained with DAPI, a DNA-binding dye, to visualize the full length of the chromosomes (dark blue). Fluorescence microscopy shows that the simple-sequence probe hybridizes primarily to one end of the telocentric mouse chromosomes (i.e., chromosomes in which the centromeres are located near one end). [Courtesy of Sabine Mal, Ph.D., Manitoba Institute of Cell Biology, Canada.]

the proper segregation of chromosomes to daughter cells during mitosis. Simple-sequence DNA is also found in long tandem repeats at the ends of chromosomes, the telomeres, where they function to maintain chromosome ends and prevent their joining to the ends of other DNA molecules, as discussed further in the last section of this chapter.

DNA Fingerprinting Depends on Differences in Length of Simple-Sequence DNAs

Within a species, the nucleotide sequences of the repeat units composing simple-sequence DNA tandem arrays are highly conserved among individuals. In contrast, the *number* of repeats, and thus the length of simple-sequence tandem arrays containing the same repeat unit, is quite variable among individuals. These differences in length are thought to result from unequal crossing over within regions of simple-sequence DNA during meiosis. As a consequence of this unequal crossing over, the lengths of some tandem arrays are unique in each individual.

In humans and other mammals, some of the simple-sequence DNA exists in relatively short 1- to 5-kb regions made up of 20–50 repeat units, each containing $\approx$ 14–100 base pairs. These regions are called *minisatellites*, in contrast to microsatellites made up of tandem repeats of 1–13 base pairs. Even slight differences in the total lengths of various minisatellites from different individuals can be detected by Southern blotting (see Figure 5-26). This technique was exploited in the first application of *DNA fingerprinting*, which was developed to detect DNA *polymorphisms* (i.e., differences in sequence between individuals of the same species, Figure 6-7). Today, the far more sensitive technique of polymerase chain reaction (PCR, Figure 5-20) is generally used in forensic genetic testing. Microsatellite DNA sequences of short tandem repeats of four bases in $\approx$ 30–50 copies are usually analyzed today. The exact number of repeats generally varies on the two homologous chromosomes of an individual where they occur (one inherited from the mother and one from the father) and on the Y chromosome in males. A mixture of pairs of PCR primers that hybridize to unique sequences flanking 13 of these short tandem repeats and a Y-chromosome short tandem repeat are used to amplify DNA in a sample. The resulting mixture of PCR product lengths is unique in the human population, except for identical twins. The use of PCR methods allows analysis of minute amounts of DNA, and individuals can be distinguished more precisely and reliably than by conventional fingerprinting.

Unclassified Spacer DNA Occupies a Significant Portion of the Genome

As Table 6.1 shows, $\approx$ 25 percent of human DNA lies between transcription units and is not repeated anywhere else in the genome. Much of this DNA probably arose from ancient transposable elements that have accumulated so many mutations over evolutionary time that they can no longer be recognized as having arisen from this source (see Section 6.3). Transcription-control regions on the order of 50–200 base

(a) Paternity determination

(b) Criminal identification

FIGURE 6-7 Distinguishing individuals by DNA fingerprinting.

(a) In this analysis of paternity, several minisatellite repeat lengths were determined by Southern blot analysis of restriction enzyme–digested genomic DNA and hybridization with a probe for a sequence shared by several minisatellite sequences. This generated hypervariable multiband patterns for each individual called “DNA fingerprints.” Lane M shows the pattern of restriction fragment bands using the mother’s DNA; C, using the child’s DNA; and F1 and F2 using DNA from two potential fathers. The child has minisatellite repeat lengths inherited from either the mother or F1, demonstrating that F1 is the father. Arrows indicate restriction fragments from F1, but not F2, found in the child’s DNA. (b) In these “DNA fingerprints” of a specimen isolated from a rape victim and three men suspected of the crime, it is clear that minisatellite repeat lengths in the specimen match those of suspect 1. The victim’s DNA was included in the analysis to ensure that the specimen DNA was not contaminated with DNA from the victim. [From T. Strachan and A. P. Read, *Human Molecular Genetics* 2, 1999, John Wiley & Sons.]

pairs in length that help to regulate transcription from distant promoters also occur in these long stretches of unclassified spacer DNA. In some cases, sequences of this seemingly nonfunctional DNA are nonetheless conserved during evolution, indicating that they may perform a significant function that is not yet understood. For example, they may contribute to the structures of chromosomes discussed in Section 6.7.

KEY CONCEPTS of Section 6.2

Chromosomal Organization of Genes and Noncoding DNA

- In the genomes of prokaryotes and most lower eukaryotes, which contain few nonfunctional sequences, coding regions are densely arrayed along the genomic DNA.

- In contrast, vertebrate and higher plant genomes contain many sequences that do not code for RNAs or have any regulatory function. Much of this nonfunctional DNA is composed of repeated sequences. In humans, only about 1.5 percent of total DNA (the exons) actually encodes proteins or functional RNAs.

- Variation in the amount of nonfunctional DNA in the genomes of various species is largely responsible for the lack of a consistent relationship between the amount of DNA in the haploid chromosomes of an animal or plant and its phylogenetic complexity.

- Eukaryotic genomic DNA consists of three major classes of sequences: genes encoding proteins and functional RNAs, repetitive DNA, and spacer DNA (see Table 6-1).

- Simple-sequence DNA, short sequences repeated in long tandem arrays, is preferentially located in centromeres, telomeres, and specific locations within the arms of particular chromosomes.

- The length of a particular simple-sequence tandem array is quite variable between individuals in a species, probably because of unequal crossing over during meiosis. Differences in the lengths of some simple-sequence tandem arrays form the basis for DNA fingerprinting (see Figure 6.7).

6.3 Transposable (Mobile) DNA Elements

Interspersed repeats, the second type of repetitive DNA in eukaryotic genomes, is composed of a very large number of copies of relatively few sequence families (see Table 6-1). Also known as *moderately repeated DNA*, or *intermediate-repeat DNA*, these sequences are interspersed throughout mammalian genomes and make up ≈ 25 –50 percent of mammalian DNA (≈ 45 percent of human DNA).

Because interspersed repeats have the unique ability to “move” in the genome, they are collectively referred to as transposable DNA elements or mobile DNA elements (we use these terms interchangeably). Although transposable DNA elements originally were discovered in eukaryotes, they also are found in prokaryotes. The process by which these sequences are copied and inserted into a new site in the genome is **transposition**. Transposable DNA elements are essentially molecular symbiotes that in most cases appear to have no specific function in the biology of their host organisms, but exist only to maintain themselves. For this reason, Francis Crick referred to them as “selfish DNA.”

When transposition occurs in germ cells, the transposed sequences at their new sites are passed on to succeeding generations. In this way, mobile elements have multiplied and slowly accumulated in eukaryotic genomes over evolutionary time. Since mobile elements are eliminated from eukaryotic genomes very slowly, they now constitute a significant portion of the genomes of many eukaryotes.

Not only are mobile elements the source for much of the DNA in our genomes, they also provided a second mechanism, in addition to meiotic recombination, for bringing about chromosomal DNA rearrangements during evolution (see Figure 6-2). One reason for this is that during transposition of a particular mobile element, adjacent DNA sometimes also is mobilized (see Figure 6-19 later in the chapter). Transpositions occur rarely: in humans, about one new germ-line transposition for every eight individuals. Since 98.5 percent of our DNA is noncoding, most transpositions have no deleterious effects. But over time they played an essential part in the evolution of genes having multiple exons and of genes whose expression is restricted to specific cell types or developmental periods. In other words, although transposable elements probably evolved as cellular symbiotes, they have had an important function in the evolution of complex, multicellular organisms.

Transposition also may occur within a somatic cell; in this case the transposed sequence is transmitted only to the daughter cells derived from that cell. In rare cases, such somatic-cell transposition may lead to a somatic-cell mutation with detrimental phenotypic effects, for example, the inactivation of a tumor-suppressor gene (Chapter 24). In this section, we first describe the structure and transposition mechanisms of the major types of transposable DNA elements and then consider their likely role in evolution.

Movement of Mobile Elements Involves a DNA or an RNA Intermediate

Barbara McClintock discovered the first mobile elements while doing classical genetic experiments in maize (corn) during the 1940s. She characterized genetic entities that could move into and back out of genes, changing the phenotype of corn kernels. Her theories were very controversial until similar mobile elements were discovered in bacteria, where they were characterized as specific DNA sequences, and the molecular basis of their transposition was deciphered.

As research on mobile elements progressed, they were found to fall into two categories: (1) those that transpose directly as DNA and (2) those that transpose via an RNA intermediate transcribed from the mobile element by an RNA polymerase and then converted back into double-stranded DNA by a reverse transcriptase (Figure 6-8). Mobile elements that transpose directly as DNA are generally referred to as **DNA transposons**, or simply **transposons**. Eukaryotic DNA transposons excise themselves from one place in the genome, leaving that site and moving to another. Mobile elements that transpose to new sites in the genome via an RNA intermediate are called **retrotransposons**. Retrotransposons make an RNA copy of themselves and introduce this new copy into another site in the genome, while also remaining at their original location. The movement of retrotransposons is analogous to the

FIGURE 6-8 Two major classes of mobile elements. (a) Eukaryotic DNA transposons (orange) move via a DNA intermediate, which is excised from the donor site. (b) Retrotransposons (green) are first transcribed into an RNA molecule, which then is reverse-transcribed into double-stranded DNA. In both cases, the double-stranded DNA intermediate is integrated into the target-site DNA to complete movement. Thus DNA transposons move by a cut-and-paste mechanism, whereas retrotransposons move by a copy-and-paste mechanism.

infectious process of retroviruses (Figure 4-49). Indeed, retroviruses can be thought of as retrotransposons that evolved genes encoding viral coats, thus allowing them to transpose between cells. Retrotransposons can be further classified on the basis of their specific mechanism of transposition. To summarize, DNA transposons can be thought of as transposing by a “cut-and-paste” mechanism, while retrotransposons move by a “copy-and-paste” mechanism in which the copy is an RNA intermediate.

DNA Transposons Are Present in Prokaryotes and Eukaryotes

Most mobile elements in bacteria transpose directly as DNA. In contrast, most mobile elements in eukaryotes are retrotransposons, but eukaryotic DNA transposons also occur. Indeed, the original mobile elements discovered by Barbara McClintock are DNA transposons.

Bacterial Insertion Sequences The first molecular understanding of mobile elements came from the study of certain *E. coli* mutations caused by the spontaneous insertion of a DNA sequence, $\approx 1\text{--}2\text{ kb}$ long, into the middle of a gene. These inserted stretches of DNA are called *insertion sequences*, or *IS elements*. So far, more than 20 different IS elements have been found in *E. coli* and other bacteria.

Transposition of an IS element is a very rare event, occurring in only one in $10^5\text{--}10^7$ cells per generation, depending on the IS element. Often, transpositions inactivate essential genes, killing the host cell and the IS elements it carries. Therefore, higher rates of transposition would probably result in too great a mutation rate for the host organism to survive. However, since IS elements transpose more or less randomly, some transposed sequences enter nonessential regions of the genome (e.g., regions between genes), allowing the cell to survive. At a very low rate of transposition, most host cells survive and therefore propagate the symbiotic IS element. IS elements also can insert into plasmids or lysogenic viruses, and thus be transferred to other cells. In this way, IS elements can transpose into the chromosomes of virgin cells.

The general structure of IS elements is diagrammed in Figure 6-9. An *inverted repeat* of ≈ 50 base pairs is invariably present at each end of an insertion sequence. In an inverted repeat, the 5'→3' sequence on one strand is repeated on the other strand, such as

Between the inverted repeats is a region that encodes *transposase*, an enzyme required for transposition of the IS element to a new site. The transposase is expressed very rarely, accounting for the very low frequency of transposition. An important hallmark of IS elements is the presence of a short *direct-repeat sequence*, containing 5–11 base pairs, depending

FIGURE 6-9 General structure of bacterial IS elements. The relatively large central region of an IS element, which encodes one or two enzymes required for transposition, is flanked by an inverted repeat at each end. The sequences of the inverted repeats are nearly identical, but they are oriented in opposite directions. The sequence is characteristic of a particular IS element. The 5' and 3' short *direct* (as opposed to *inverted*) repeats are not transposed with the insertion element; rather, they are insertion-site sequences that become duplicated, with one copy at each end, during insertion of a mobile element. The length of the direct repeats is constant for a given IS element, but their sequence depends on the site of insertion and therefore varies with each transposition of the IS element. Arrows indicate sequence orientation. The regions in this diagram are not to scale; the coding region makes up most of the length of an IS element.

on the IS element, immediately adjacent to both ends of the inserted element. The *length* of the direct repeat is characteristic of each type of IS element, but its *sequence* depends on the target site where a particular copy of the IS element inserted. When the sequence of a mutated gene containing an IS element is compared with the wild-type gene sequence, only one copy of the short direct-repeat sequence is found in the wild-type gene. Duplication of this target-site sequence to create the second direct repeat adjacent to an IS element occurs during the insertion process.

As depicted in Figure 6-10, transposition of an IS element occurs by a “cut-and-paste” mechanism. Transposase performs three functions in this process: it (1) precisely excises the IS element in the donor DNA, (2) makes staggered cuts in a short sequence in the target DNA, and (3) ligates the 3' termini of the IS element to the 5' ends of the cut donor DNA. Finally, a host-cell DNA polymerase fills in the single-stranded gaps, generating the short direct repeats that flank IS elements, and DNA ligase joins the free ends.

Eukaryotic DNA Transposons McClintock’s original discovery of mobile elements came from observation of spontaneous mutations in maize that affect production of enzymes required to make anthocyanin, a purple pigment in maize kernels. Mutant kernels are white, and wild-type kernels are purple. One class of these mutations is revertible at high frequency, whereas a second class of mutations does not revert unless they occur in the presence of the first class of mutations. McClintock called the agent responsible for the first class of mutations the *activator (Ac) element* and those responsible for the second class *dissociation (Ds) elements* because they also tended to be associated with chromosome breaks.

Many years after McClintock’s pioneering discoveries, cloning and sequencing revealed that Ac elements are equivalent to bacterial IS elements. Like IS elements, they contain

FIGURE 6-10 Model for transposition of bacterial insertion sequences. Step **1**: Transposase, which is encoded by the IS element (IS10 in this example), cleaves both strands of the donor DNA next to the inverted repeats (dark red), excising the IS10 element. At a largely random target site; transposase makes staggered cuts in the target DNA. In the case of IS10, the two cuts are 9 bp apart. Step **2**: Ligation of the 3' ends of the excised IS element to the staggered sites in the target DNA also is catalyzed by transposase. Step **3**: The 9-bp gaps of single-stranded DNA left in the resulting intermediate are filled in by a cellular DNA polymerase; finally, cellular DNA ligase forms the 3'→5' phosphodiester bonds between the 3' ends of the extended target DNA strands and the 5' ends of the IS10 strands. This process results in duplication of the target-site sequence on each side of the inserted IS element. Note that the length of the target site and IS10 are not to scale. [See H. W. Benjamin and N. Kleckner, 1989, *Cell* **59**:373; and 1992, *Proc. Nat'l Acad. Sci. USA* **89**:4648.]

inverted terminal repeat sequences that flank the coding region for a transposase, which recognizes the terminal repeats and catalyzes transposition to a new site in DNA. Ds elements are deleted forms of the Ac element in which a portion of the sequence encoding transposase is missing. Because it does not encode a functional transposase, a Ds element cannot move by itself. However, in plants that carry the Ac element and thus express a functional transposase, Ds elements can be

transposed because they retain the inverted terminal repeats recognized by the transposase.

Since McClintock's early work on mobile elements in corn, transposons have been identified in other eukaryotes. For instance, approximately half of all the spontaneous mutations observed in *Drosophila* are due to the insertion of mobile elements. Although most of the mobile elements in *Drosophila* function as retrotransposons, at least one—the *P* element—functions as a DNA transposon, moving by a mechanism similar to that used by bacterial insertion sequences. Current methods for constructing transgenic *Drosophila* depend on engineered, high-level expression of the P-element transposase and use of the P-element inverted terminal repeats as targets for transposition, as discussed in Chapter 5 (see Figure 5-22).

DNA transposition by the cut-and-paste mechanism can result in an increase in the copy number of a transposon if it occurs during the S phase of the cell cycle, when DNA synthesis occurs. An increase in the copy number happens when the donor DNA is from one of the two daughter DNA molecules in a region of a chromosome that has replicated and the target DNA is in the region that has not yet replicated. When DNA replication is complete at the end of the S phase, the target DNA in its new location is also replicated, resulting in a net increase in the total number of these transposons in the cell (Figure 6-11). When such a transposition occurs during the S phase preceding meiosis, one of the four germ cells produced contains the extra copy of the transposon. Repetition of this process over evolutionary time has resulted in the accumulation of large numbers of DNA transposons in the genomes of some organisms. Human DNA contains about 300,000 copies of full-length and deleted DNA transposons,

FIGURE 6-11 Mechanism for increasing DNA-transposon copy number. If a DNA transposon that transposes by a cut-and-paste mechanism (see Figure 6-10) transposes during S phase from a region of the chromosome that has replicated to a region that has not yet replicated, then, when chromosomal replication is completed, one of the two daughter chromosomes will have a net increase of one transposon insertion.

amounting to ≈ 3 percent of human DNA. As we will see shortly, this mechanism can lead to the transposition of genomic DNA as well as the transposon itself.

LTR Retrotransposons Behave Like Intracellular Retroviruses

The genomes of all eukaryotes studied, from yeast to humans, contain retrotransposons, mobile DNA elements that transpose through an RNA intermediate utilizing a reverse transcriptase (see Figure 6-8b). These mobile elements are divided into two major categories, those containing and those lacking long terminal repeats (LTRs). LTR retrotransposons, which we discuss here, are common in yeast (e.g., Ty elements) and in *Drosophila* (e.g., *copia* elements). Although less abundant in mammals than non-LTR retrotransposons, LTR retrotransposons nonetheless constitute ≈ 8 percent of human genomic DNA. In mammals, retrotransposons lacking LTRs are the most common type of mobile element; these are described in the next section.

The general structure of LTR retrotransposons found in eukaryotes is depicted in Figure 6-12. In addition to short 5' and 3' direct repeats typical of all transposons, these retrotransposons are marked by the presence of LTRs flanking the central protein-coding region. These long direct terminal repeats, containing ≈ 250 –600 base pairs depending on the type of LTR retrotransposon, are characteristic of integrated retroviral DNA and are critical to the life cycle of retroviruses. In addition to sharing LTRs with retroviruses, LTR retrotransposons encode all the proteins of the most common type of retroviruses, except for the envelope proteins. Lacking these envelope proteins, LTR retrotransposons cannot bud from their host cell and infect other cells; however, they can transpose to new sites in the DNA of their host cell. Because of their clear relationship with retroviruses, this class of retrotransposons is often called *retrovirus-like elements*.

A key step in the retroviral life cycle is formation of retroviral genomic RNA from integrated retroviral DNA (see Figure 4-49). This process serves as a model for generation of the RNA intermediate during transposition of LTR retrotransposons. As depicted in Figure 6-13, the leftward retro-

FIGURE 6-12 General structure of eukaryotic LTR retrotransposons. The central protein-coding region is flanked by two long terminal repeats (LTRs), which are element-specific direct repeats. Like other mobile elements, integrated retrotransposons have short target-site direct repeats at each end. Note that the different regions are not drawn to scale. The protein-coding region constitutes 80 percent or more of a retrotransposon and encodes reverse transcriptase, integrase, and other retroviral proteins.

FIGURE 6-13 Generation of retroviral genomic RNA from integrated retroviral DNA. The left LTR directs cellular RNA polymerase to initiate transcription at the first nucleotide of the left R region. The resulting primary transcript extends beyond the right LTR. The right LTR, now present in the RNA primary transcript, directs cellular enzymes to cleave the primary transcript at the last nucleotide of the right R region and to add a poly(A) tail, yielding a retroviral RNA genome with the structure shown at the top of Figure 6-14. A similar mechanism is thought to generate the RNA intermediate during transposition of retrotransposons. The short direct-repeat sequences (black) of target-site DNA are generated during integration of the retroviral DNA into the host-cell genome.

viral LTR functions as a promoter that directs host-cell RNA polymerase to initiate transcription at the 5' nucleotide of the R sequence. After the entire downstream retroviral DNA has been transcribed, the RNA sequence corresponding to the rightward LTR directs host-cell RNA-processing enzymes to cleave the primary transcript and add a poly(A) tail at the 3' end of the R sequence. The resulting retroviral RNA genome, which lacks a complete LTR, exits the nucleus and is packaged into a virion that buds from the host cell.

After a retrovirus infects a cell, reverse transcription of its RNA genome by the retrovirus-encoded reverse transcriptase yields a double-stranded DNA containing complete LTRs (Figure 6-14). This DNA synthesis takes place in the

FIGURE 6-14 Model for reverse transcription of retroviral genomic RNA into DNA. In this model, a complicated series of nine events generates a double-stranded DNA copy of the single-stranded RNA genome of a retrovirus. The genomic RNA is packaged in the virion with a retrovirus-specific cellular tRNA hybridized to a complementary sequence near its 5' end called the *primer-binding site* (PBS). The retroviral RNA has a short direct-repeat terminal sequence (R) at each end. The overall reaction is carried out by reverse transcriptase, which catalyzes polymerization of deoxyribonucleotides. RNaseH digests the RNA strand in a DNA-RNA hybrid. The entire process yields a double-stranded DNA molecule that is longer than the template RNA and has a long terminal repeat (LTR) at each end. The different regions are not shown to scale. The PBS and R regions are actually much shorter than the U5 and U3 regions, and the central coding region is very much longer than the other regions. [See E. Gilboa et al., 1979, *Cell* 18:93.]

FOCUS ANIMATION: Retroviral Reverse Transcription

EXPERIMENTAL FIGURE 6-15 The yeast Ty element transposes through an RNA intermediate. When yeast cells are transformed with a Ty-containing plasmid, the Ty element can transpose to new sites, although normally this occurs at a low rate. Using the elements diagrammed at the top, researchers engineered two different recombinant plasmid vectors containing recombinant Ty elements adjacent to a galactose-sensitive promoter. These plasmids were transformed into yeast cells, which were grown in a galactose-containing and a nongalactose medium. In experiment 1, growth of cells in galactose-containing medium resulted in many more transpositions than in nongalactose medium, indicating that transcription into an mRNA intermediate is required for Ty transposition. In experiment 2, an intron from an unrelated yeast gene was inserted into the putative protein-coding region of the recombinant galactose-responsive Ty element. The observed absence of the intron in transposed Ty elements is strong evidence that transposition involves an mRNA intermediate from which the intron was removed by RNA splicing, as depicted in the box on the right. In contrast, eukaryotic DNA transposons, like the Ac element of maize, contain introns within the transposase gene, indicating that they do not transpose via an RNA intermediate. [See J. Boeke et al., 1985, *Cell* 40:491.]

cytosol. The double-stranded DNA with an LTR at each end is then transported into the nucleus in a complex with integrase, another enzyme encoded by retroviruses. Retroviral integrases are closely related to the transposases encoded by DNA transposons and use a similar mechanism to insert the double-stranded retroviral DNA into the host-cell genome. In this process, short direct repeats of the target-site sequence are generated at either end of the inserted viral DNA sequence. Although the mechanism of reverse transcription is complex, it is a critical aspect of the retrovirus life cycle. The process generates the complete 5' LTR that functions as a promoter for initiation of transcription precisely at the 5' nucleotide of the R sequence, while the complete 3' LTR functions as a poly(A) site leading to polyadenylation precisely at the 3' nucleotide of the R sequence. Consequently, no nucleotides are lost from an LTR retrotransposon as it undergoes successive rounds of insertion, transcription, reverse transcription, and re-insertion at a new site.

As noted above, LTR retrotransposons encode reverse transcriptase and integrase. By analogy with retroviruses, these mobile elements move by a "copy-and-paste" mechanism whereby reverse transcriptase converts an RNA copy of a donor element into DNA, which is inserted into a target site by integrase. The experiments depicted in Figure 6-15 provided strong evidence for the role of an RNA intermediate in transposition of Ty elements in yeast.

The most common LTR retrotransposons in humans are called ERVs, for *endogenous retroviruses*. Most of the 443,000 ERV-related DNA sequences in the human genome consist only of isolated LTRs. These are derived from full-length proviral DNA by homologous recombination between the two LTRs, resulting in deletion of the internal retroviral sequences. Isolated LTRs such as these cannot be transposed to a new position in the genome, but recombination between homologous LTRs at different positions in the genome have likely contributed to the chromosomal DNA rearrangements leading to gene and exon duplications, the evolution of proteins with new combinations of exons, and, as we will see in Chapter 7, the evolution of complex control of gene expression.

Non-LTR Retrotransposons Transpose by a Distinct Mechanism

The most abundant mobile elements in mammals are retrotransposons that lack LTRs, sometimes called *nonviral retrotransposons*. These moderately repeated DNA sequences form two classes in mammalian genomes: *long interspersed elements (LINEs)* and *short interspersed elements (SINEs)*. In humans, full-length LINEs are ≈ 6 kbp long, and SINEs are ≈ 300 bp long (see Table 6-1). Repeated sequences with the characteristics of LINEs have been observed in protozoans, insects, and plants, but for unknown reasons they are particularly abundant in the genomes of mammals. SINEs also are found primarily in mammalian DNA. Large numbers of LINEs and SINEs in higher eukaryotes have accumulated over evolutionary time by repeated copying of

FIGURE 6-16 General structure of a LINE, a non-LTR retrotransposon. Mammalian DNA carries two classes of non-LTR retrotransposons, LINEs and SINEs. LINE structure is depicted here. The length of the target-site direct repeats varies among copies of the element at different sites in the genome. Although the full-length L1 sequence is ≈6 kb long, variable amounts of the left end are absent at over 90 percent of the sites where this mobile element is found. The shorter open reading frame (ORF1), ≈1 kb in length, encodes an RNA-binding protein. The longer ORF2, ≈4 kb in length, encodes a bifunctional protein with reverse transcriptase and DNA endonuclease activity. Note that LINEs lack the long terminal repeats found in LTR retrotransposons.

sequences at a few positions in the genome and insertion of the copies into new positions.

LINEs Human DNA contains three major families of LINE sequences that are similar in their mechanism of transposition but differ in their sequences: L1, L2, and L3. Only members of the L1 family transpose in the contemporary human genome. Apparently there are no remaining functional copies of L2 or L3. LINE sequences are present at ≈900,000 sites in the human genome, accounting for a staggering 21 percent of total human DNA. The general structure of a complete LINE is diagrammed in Figure 6-16. LINEs usually are flanked by short direct repeats, the hallmark of mobile elements, and contain two long open reading frames (ORFs). ORF1, ≈1 kb long, encodes an RNA-binding protein. ORF2, ≈4 kb long, encodes a protein that has a long region of homology with the reverse transcriptases of retroviruses and LTR retrotransposons, but also exhibits DNA endonuclease activity.

 Evidence for the mobility of L1 elements first came from analysis of DNA cloned from humans with certain genetic diseases such as hemophilia and myotonic dystrophy. DNA from these patients was found to carry mutations resulting from insertion of an L1 element into a gene, whereas no such element occurred within this gene in either parent. About 1 in 600 mutations that cause significant disease in humans are due to L1 transpositions or SINE transpositions that are catalyzed by L1-encoded proteins. Later experiments similar to those just described with yeast Ty elements (see Figure 6-15) confirmed that L1 elements transpose through an RNA intermediate. In these experiments, an intron was introduced into a cloned mouse L1 element, and the recombinant L1 element was stably transformed into cultured hamster cells. After several cell doublings, a PCR-amplified fragment corresponding to the L1 element but lacking the inserted intron was detected in the cells. This finding strongly suggests that, over time, the recombinant L1

element containing the inserted intron had transposed to new sites in the hamster genome through an RNA intermediate that underwent RNA splicing to remove the intron. ■

Since LINEs do not contain LTRs, their mechanism of transposition through an RNA intermediate differs from that of LTR retrotransposons. ORF1 and ORF2 proteins are translated from a LINE RNA. In vitro studies indicate that transcription by RNA polymerase is directed by promoter sequences at the left end of integrated LINE DNA. LINE RNA is polyadenylated by the same post-transcriptional mechanism that polyadenylates other mRNAs. The LINE RNA then is exported into the cytosol, where it is translated into ORF1 and ORF2 proteins. Multiple copies of ORF1 protein then bind to the LINE RNA, and ORF2 protein binds to the poly(A) tail. The LINE RNA is then transported back into the nucleus as a complex with ORF1 and ORF2 proteins, and is reverse-transcribed into LINE DNA in the nucleus by ORF2. The mechanism involves staggered cleavage of cellular DNA at the insertion site, followed by priming of reverse transcription by the resulting cleaved cellular DNA as detailed in Figure 6-17. The complete process results in insertion of a copy of the original LINE retrotransposon into a new site in chromosomal DNA. A short direct repeat is generated at the insertion site because of the initial staggered cleavage of the two chromosomal DNA strands.

As noted already, the DNA form of an LTR retrotransposon is synthesized from its RNA form in the cytosol using a cellular tRNA as a primer for reverse transcription of the first strand of DNA (see Figure 6-14). The resulting double-stranded DNA with long terminal repeats is then transported into the nucleus, where it is integrated into chromosomal DNA by a retrotransposon-encoded integrase. In contrast, the DNA form of a non-LTR retrotransposon is synthesized in the nucleus. The synthesis of the first strand of the non-LTR retroviral DNA by ORF2, a reverse transcriptase, is primed by the 3' end of cleaved chromosomal DNA, which base-pairs with the poly(A) tail of the non-LTR retroviral RNA (see Figure 6-17, step 4). Since its synthesis is primed by the cut end of a cleaved chromosome, and synthesis of the other strand of the non-LTR retrotransposon DNA is primed by the 3' end of chromosomal DNA on the other side of the initial cut in chromosomal DNA (step 6), the mechanism of synthesis results in integration of the non-LTR retrotransposon DNA. There is no need for an integrase to insert the non-LTR retrotransposon DNA.

The vast majority of LINEs in the human genome are truncated at their 5' end, suggesting that reverse transcription terminated before completion and the resulting fragments extending variable distances from the poly(A) tail were inserted. Because of this shortening, the average size of LINE elements is only about 900 base pairs, even though the full-length sequence is ≈6 kb long. Truncated LINE elements, once formed, probably are not further transposed because they lack a promoter for formation of the RNA intermediate in transposition. In addition to the fact that most L1 insertions

FIGURE 6-17 Proposed mechanism of LINE reverse transcription and integration. Only ORF2 protein is represented. Newly synthesized LINE DNA is shown in black. ORF1 and ORF2 proteins, produced by translation of LINE RNA in the cytoplasm, bind to LINE RNA and transport it into the nucleus. Step **1**: In the nucleus, ORF2 makes staggered cuts in AT-rich target-site DNA, generating the DNA 3'-OH ends indicated by blue arrowheads. Step **2**: The 3' end of the T-rich DNA strand hybridizes to the poly(A) tail of the LINE RNA and primes DNA synthesis by ORF2. Step **3**: ORF2 extends the DNA strand using the LINE RNA as template. Steps **4** and **5**: When synthesis of the LINE DNA bottom strand reaches the 5' end of the LINE RNA template, ORF2 extends the newly synthesized LINE DNA using as template the top-strand cellular DNA generated by the initial ORF2 staggered cleavage. Step **6**: A cellular DNA polymerase extends the 3' end of the top strand generated by the initial ORF2 staggered cut, using the newly synthesized bottom-strand LINE DNA as template. The LINE RNA is digested as the DNA polymerase extends the upper-strand DNA, just as occurs during removal of lagging-strand primer RNA during cellular DNA synthesis (Figure 4-33). Step **7**: The 3' end of the newly synthesized DNA strands are ligated to the 5' ends of the cellular DNA strands as in lagging-strand cellular DNA synthesis. [Adapted from D. D. Luan et al., 1993, *Cell* 72:595.]

are truncated, nearly all the full-length elements contain stop codons and frameshift mutations in ORF1 and ORF2; these mutations probably have accumulated in most LINE sequences over evolutionary time. As a result, only ≈ 0.01 percent of the LINE sequences in the human genome are full-length, with intact open reading frames for ORF1 and ORF2, representing ≈ 60 –100 in total number.

SINEs The second most abundant class of mobile elements in the human genome, SINEs constitute ≈ 13 percent of total human DNA. Varying in length from about 100 to 400 base pairs, these retrotransposons do not encode protein, but most contain a 3' A/T-rich sequence similar to that in LINES. SINEs are transcribed by the same nuclear RNA polymerase that transcribes genes encoding tRNAs, 5S rRNAs, and other small stable RNAs. Most likely, the ORF1 and ORF2 proteins expressed from full-length LINES mediate reverse transcription and integration of SINEs by the mechanism depicted in Figure 6-17. Consequently, SINEs can be viewed as parasites of the LINE symbiotes, competing with LINE RNAs for binding and reverse transcription/integration by LINE encoded ORF1 and ORF2.

SINEs occur at about 1.6 million sites in the human genome. Of these, ≈ 1.1 million are *Alu* elements, so named because most of them contain a single recognition site for the restriction enzyme *Alu*I. *Alu* elements exhibit considerable sequence homology with and probably evolved from 7SL RNA, a cytosolic RNA in a ribonucleoprotein complex called the signal recognition particle. This abundant cytosolic ribonucleoprotein particle aids in targeting certain polypeptides to the membranes of the endoplasmic reticulum (Chapter 13). *Alu* elements are scattered throughout the human genome at sites where their insertion has not disrupted gene expression: between genes, within introns, and

in the 3' untranslated regions of some mRNAs. For instance, nine *Alu* elements are located within the human β -globin gene cluster (see Figure 6-4a). Of the one new germ-line non-LTR retrotransposition that is estimated to occur in about every eight individuals, ≈ 40 percent involve L1 elements and 60 percent involve SINEs, of which ≈ 90 percent are *Alu* elements.

Similar to other mobile elements, most SINEs have accumulated mutations from the time of their insertion in the germ line of an ancient ancestor of modern humans. Like LINES, many SINEs also are truncated at their 5' end.

Other Retroposed RNAs Are Found in Genomic DNA

In addition to the mobile elements listed in Table 6-1, DNA copies of a wide variety of mRNAs appear to have integrated into chromosomal DNA. Since these sequences lack introns and do not have flanking sequences similar to those of the functional gene copies, they clearly are not simply duplicated genes that have drifted into nonfunctionality and become pseudogenes, as discussed earlier (Figure 6-4a). Instead, these DNA segments appear to be retrotransposed copies of spliced and polyadenylated mRNA. Compared with normal genes encoding mRNAs, these inserted segments generally contain multiple mutations, which are thought to have accumulated since their mRNAs were first reverse-transcribed and randomly integrated into the genome of a germ cell in an ancient ancestor. These nonfunctional genomic copies of mRNAs are referred to as *processed pseudogenes*. Most processed pseudogenes are flanked by short direct repeats, supporting the hypothesis that they were generated by rare retrotransposition events involving cellular mRNAs.

Other interspersed repeats representing partial or mutant copies of genes encoding small nuclear RNAs (snRNAs) and tRNAs are found in mammalian genomes. Like processed pseudogenes derived from mRNAs, these nonfunctional copies of small RNA genes are flanked by short direct repeats and most likely result from rare retrotransposition events that have accumulated through the course of evolution. Enzymes expressed from a LINE are thought to have carried out all these retrotransposition events involving mRNAs, snRNAs, and tRNAs.

Mobile DNA Elements Have Significantly Influenced Evolution

Although mobile DNA elements appear to have no direct function other than to maintain their own existence, their presence has had a profound impact on the evolution of modern-day organisms. As mentioned earlier, about half the spontaneous mutations in *Drosophila* result from insertion of a mobile DNA element into or near a transcription unit. In mammals, mobile elements cause a much smaller proportion of spontaneous mutations: ≈ 10 percent in mice, and only 0.1–0.2 percent in humans. Still, mobile elements have been found in mutant alleles associated with several human genetic diseases. For example, insertions into the clotting factor IX gene cause hemophilia, and insertions into the gene encoding the muscle protein dystrophin lead to Duchenne muscular dystrophy. The genes encoding factor IX and dystrophin are both on the X chromosome. Because the male genome has only one copy of the X chromosome, transposition insertions into these genes predominantly affect males.

In lineages leading to higher eukaryotes, homologous recombination between mobile DNA elements dispersed throughout ancestral genomes may have generated gene duplications and other DNA rearrangements during evolution (see Figure 6-2b). For instance, cloning and sequencing of the β -globin gene cluster from various primate species has provided strong evidence that the human G_γ and A_γ genes arose from an unequal homologous crossover between two L1 sequences flanking an ancestral globin gene. Subsequent divergence of such duplicated genes could lead to acquisition of distinct, beneficial functions associated with each member of a gene family. Unequal crossing over between mobile elements located within introns of a particular gene could lead to the duplication of exons within that gene (see Figure 6-2a). This process most likely influenced the evolution of genes that contain multiple copies of similar exons encoding similar protein domains, such as the fibronectin gene (see Figure 4-16).

Some evidence suggests that during the evolution of higher eukaryotes, recombination between mobile DNA elements (e.g., *Alu* elements) in introns of *two separate* genes also occurred, generating new genes made from novel combinations of preexisting exons (Figure 6-18). This evolutionary process, termed **exon shuffling**, may have occurred during evolution of the genes encoding tissue plasminogen activator,

FIGURE 6-18 Exon shuffling via recombination between homologous interspersed repeats. Recombination between interspersed repeats in the introns of separate genes produces transcription units with a new combination of exons. In the example shown here, a double crossover between two sets of *Alu* repeats results in an exchange of exons between the two genes.

FIGURE 6-19 Exon shuffling by transposition. (a) Transposition of an exon flanked by homologous DNA transposons into an intron on a second gene. As we saw in Figure 6-10, step 1, transposase can recognize and cleave the DNA at the ends of the transposon inverted repeats. In gene 1, if the transposase cleaves at the left end of the transposon on the left and at the right end of the transposon on the right, it can transpose all the intervening DNA, including the exon from gene 1, to a new site in an intron of gene 2. The net result is an insertion of the exon from gene 1 into gene 2. (b) Integration of an exon into another gene via LINE transposition. Some LINEs have weak poly(A) signals. If such a LINE is in the 3'-most intron of gene 1, during transposition its transcription may continue beyond its own poly(A) signals and extend into the 3' exon, transcribing the cleavage and polyadenylation signals of gene 1 itself. This RNA can then be reverse-transcribed and integrated by the LINE ORF2 protein (Figure 6-17) into an intron on gene 2, introducing a new 3' exon (from gene 1) into gene 2.

the Neu receptor, and epidermal growth factor, which all contain an EGF domain (see Figure 3-11). In this case, exon shuffling presumably resulted in insertion of an EGF domain-encoding exon into an intron of the ancestral form of each of these genes.

Both DNA transposons and LINE retrotransposons have been shown to occasionally carry unrelated flanking sequences when they transpose to new sites by the mechanisms diagrammed in Figure 6-19. These mechanisms likely also contributed to exon shuffling during the evolution of contemporary genes.

In addition to causing changes in coding sequences in the genome, recombination between mobile elements and transposition of DNA adjacent to DNA transposons and retrotransposons likely played a significant role in the evolution of regulatory sequences that control gene expression. As noted earlier, eukaryotic genes have transcription-control regions called enhancers that can operate over distances of tens of thousands of base pairs. Transcription of many genes is controlled through the combined effects of several enhancer elements. Insertion of mobile elements near such transcription-control regions probably contributed to the evolution of new combinations of enhancer sequences. These in turn control which specific genes are expressed in particular cell types and the amount of the encoded protein

produced in modern organisms, as we discuss in the next chapter.

These considerations suggest that the early view of mobile DNA elements as completely selfish molecular parasites misses the mark. Rather, they have contributed profoundly to the evolution of higher organisms by promoting (1) the generation of gene families via gene duplication, (2) the creation of new genes via shuffling of preexisting exons, and (3) formation of more complex regulatory regions that provide multifaceted control of gene expression. Today, researchers are attempting to harness transposition mechanisms for inserting therapeutic genes into patients as a form of gene therapy.

A process analogous to that shown in Figure 6-19a is largely responsible for the rapid spread of antibiotic resistance among pathogenic bacteria, a major problem in modern medicine. Bacterial genes encoding enzymes that inactivate antibiotics (drug resistance genes) have been flanked by insertion sequences generating drug resistance transposons. The widespread use of antibiotics in medicine, often unnecessarily in the treatment of viral infections where they have no effect, and to prevent infections of healthy agricultural animals, has led to the selection of such drug resistance transposons that have inserted into conjugating plasmids. Conjugating plasmids encode proteins that result in the

replication and transfer of the plasmid to related bacteria through a complex macromolecular tube called a pilus. These plasmids, called R factors (for drug resistance), can contain multiple drug resistance genes introduced by transposition and selected in environments where antibiotics are used to sterilize surfaces, such as hospitals. These have led to the rapid spread of resistance to multiple antibiotics between pathogenic bacteria. Coping with the spread of R factors is a major challenge for modern medicine. ■

KEY CONCEPTS of Section 6.3

Transposable (Mobile) DNA Elements

- Transposable DNA elements are moderately repeated sequences interspersed at multiple sites throughout the genomes of higher eukaryotes. They are present less frequently in prokaryotic genomes.
- DNA transposons move to new sites directly as DNA; retrotransposons are first transcribed into an RNA copy of the element, which then is reverse-transcribed into DNA (see Figure 6-8).
- A common feature of all mobile elements is the presence of short direct repeats flanking the sequence.
- Enzymes encoded by transposons themselves catalyze insertion of these sequences at new sites in genomic DNA.
- Although DNA transposons, similar in structure to bacterial IS elements, occur in eukaryotes (e.g., the *Drosophila* P element), retrotransposons generally are much more abundant, especially in vertebrates.
- LTR retrotransposons are flanked by long terminal repeats (LTRs), similar to those in retroviral DNA; like retroviruses, they encode reverse transcriptase and integrase. They move in the genome by being transcribed into RNA, which then undergoes reverse transcription in the cytosol, nuclear import of the resulting DNA with LTRs, and integration into a host-cell chromosome (see Figure 6-14).
- Non-LTR retrotransposons, including long interspersed elements (LINEs) and short interspersed elements (SINEs), lack LTRs and have an A/T-rich stretch at one end. They are thought to move by a nonviral retrotransposition mechanism mediated by LINE-encoded proteins involving priming of reverse transcription by chromosomal DNA (see Figure 6-17).
- SINE sequences exhibit extensive homology with small cellular RNAs and are transcribed by the same RNA polymerase. *Alu* elements, the most common SINEs in humans, are ~300-bp sequences found scattered throughout the human genome.
- Some interspersed repeats are derived from cellular RNAs that were reverse-transcribed and inserted into genomic DNA at some time in evolutionary history. Processed pseudogenes derived from mRNAs lack introns, a feature that

distinguishes them from pseudogenes, which arose by sequence drift of duplicated genes.

- Mobile DNA elements most likely influenced evolution significantly by serving as recombination sites and by mobilizing adjacent DNA sequences.

6.4 Organelle DNAs

Although the vast majority of DNA in most eukaryotes is found in the nucleus, some DNA is present within the mitochondria of animals, plants, and fungi, and within the chloroplasts of plants. These organelles are the main cellular sites for ATP formation, during oxidative phosphorylation in mitochondria and photosynthesis in chloroplasts (Chapter 12). Many lines of evidence indicate that mitochondria and chloroplasts evolved from eubacteria that were engulfed into ancestral cells containing a eukaryotic nucleus, forming **endosymbiotes** (Figure 6-20). Over evolutionary time, most of the bacterial genes were lost from organellar DNAs. Some, such as genes encoding proteins involved in nucleotide, lipid, and amino acid biosynthesis, were lost because their functions were provided by genes in the nucleus of the host cell. Other genes encoding components of the present-day organelles were transferred to the nucleus. However, mitochondria and chloroplasts in today's eukaryotes retain DNAs encoding some proteins essential for organellar function, as well as the ribosomal and transfer RNAs required for synthesis of these proteins. Thus eukaryotic cells have multiple genetic systems: a predominant nuclear system and secondary systems with their own DNA, ribosomes, and tRNAs in mitochondria and chloroplasts.

Mitochondria Contain Multiple mtDNA Molecules

Individual mitochondria are large enough to be seen under the light microscope, and even the mitochondrial DNA (mtDNA) can be detected by fluorescence microscopy. The mtDNA is located in the interior of the mitochondrion, the region known as the matrix (see Figure 12-6). As judged by the number of yellow fluorescent "dots" of mtDNA, a *Euglena gracilis* cell contains at least 30 mtDNA molecules (Figure 6-21).

Replication of mtDNA and division of the mitochondrial network can be followed in living cells using time-lapse microscopy. Such studies show that, in most organisms, mtDNA replicates throughout interphase. At mitosis, each daughter cell receives approximately the same number of mitochondria, but since there is no mechanism for apportioning exactly equal numbers of mitochondria to the daughter cells, some cells contain more mtDNA than others. By isolating mitochondria from cells and analyzing the DNA extracted from them, it can be seen that each mitochondrion contains

FIGURE 6-20 Endosymbiont hypothesis model of mitochondria and chloroplast evolution. Endocytosis of a bacterium by an ancestral eukaryotic cell would generate an organelle with two membranes, the outer membrane derived from the eukaryotic plasma membrane and the inner one from the bacterial membrane. Proteins localized to the ancestral bacterial membrane retain their orientation, such that the

portion of the protein once facing the extracellular space now faces the intermembrane space. Budding of vesicles from the inner chloroplast membrane, such as occurs during development of chloroplasts in contemporary plants, would generate the thylakoid membranes of chloroplasts. The organellar DNAs are indicated.

multiple mtDNA molecules. Thus the total amount of mtDNA in a cell depends on the number of mitochondria, the size of the mtDNA, and the number of mtDNA molecules per mitochondrion. Each of these parameters varies greatly between different cell types.

EXPERIMENTAL FIGURE 6-21 Dual staining reveals the multiple mitochondrial DNA molecules in a growing *Euglena gracilis* cell. Cells were treated with a mixture of two dyes: ethidium bromide, which binds to DNA and emits a red fluorescence, and DiOC₆, which is incorporated specifically into mitochondria and emits a green fluorescence. Thus the nucleus emits a red fluorescence, and areas rich in mitochondrial DNA fluoresce yellow—a combination of red DNA and green mitochondrial fluorescence. [From Y. Hayashi and K. Ueda, 1989, *J. Cell Sci.* 93:565.]

mtDNA Is Inherited Cytoplasmically

Studies of mutants in yeasts and other single-celled organisms first indicated that mitochondria exhibit *cytoplasmic inheritance* and thus must contain their own genetic system (Figure 6-22). For instance, *pette* yeast mutants exhibit structurally abnormal mitochondria and are incapable of oxidative phosphorylation. As a result, *pette* cells grow more slowly than wild-type yeasts and form smaller colonies. Genetic crosses between different (haploid) yeast strains showed that the *pette* mutation does not segregate with any known nuclear gene or chromosome. In later studies, most *pette* mutants were found to contain deletions of mtDNA.

In the mating by fusion of haploid yeast cells, both parents contribute equally to the cytoplasm of the resulting diploid; thus inheritance of mitochondria is biparental (see Figure 6-22a). In mammals and most other multicellular organisms, however, the sperm contributes little (if any) cytoplasm to the zygote, and virtually all the mitochondria in the embryo are derived from those in the egg, not the sperm. Studies in mice have shown that 99.99 percent of mtDNA is maternally inherited, but a small part (0.01 percent) is inherited from the male parent. In higher plants, mtDNA is inherited exclusively in a uniparental fashion through the female parent (egg), not the male (pollen).

The Size, Structure, and Coding Capacity of mtDNA Vary Considerably Between Organisms

Surprisingly, the size of the mtDNA, the number and nature of the proteins it encodes, and even the mitochondrial genetic code itself vary greatly between different organisms. The mtDNAs of most multicellular animals are ≈16-kb circular molecules that encode intron-less genes compactly arranged on both DNA strands. Vertebrate mtDNAs encode

FIGURE 6-22 Cytoplasmic inheritance of an mtDNA *petite* mutation in yeast.

Petite-strain mitochondria are defective in oxidative phosphorylation owing to a deletion in mtDNA. (a) Haploid cells fuse to produce a diploid cell that undergoes meiosis, during which random segregation of parental chromosomes and mitochondria containing mtDNA occurs. Note that alleles for genes in nuclear DNA (represented by large and small nuclear chromosomes colored red and blue) segregate 2:2 during meiosis (see Figure 5-5). In contrast, since yeast normally contain ≈ 50 mtDNA molecules per cell, all products of meiosis usually contain both normal and petite mtDNAs and are capable of respiration. (b) As these haploid cells grow and divide mitotically, the cytoplasm (including the mitochondria) is randomly distributed to the daughter cells. Occasionally, a cell is generated that contains only defective petite mtDNA and yields a petite colony. Thus formation of such petite cells is independent of any nuclear genetic marker.

the two rRNAs found in mitochondrial ribosomes, the 22 tRNAs used to translate mitochondrial mRNAs, and 13 proteins involved in electron transport and ATP synthesis (Chapter 12). The smallest mitochondrial genomes known are in *Plasmodium*, single-celled obligate intracellular parasites that cause malaria in humans. *Plasmodium* mtDNAs are only ≈ 6 kb, encoding five proteins and the mitochondrial rRNAs.

The mitochondrial genomes from a number of different metazoan organisms (i.e., multicellular animals) have now been cloned and sequenced, and mtDNAs from all these sources encode essential mitochondrial proteins (Figure 6-23). All proteins encoded by mtDNA are synthesized on mitochondrial ribosomes. Most mitochondrially synthesized polypeptides identified thus far are subunits of multimeric complexes used in electron transport, ATP synthesis, or insertion of proteins into the inner mitochondrial membrane or intermembrane space. However, most of the proteins localized in mitochondria, such as those involved in the processes listed at the top of Figure 6-23, are encoded by nuclear genes, synthesized on cytosolic ribosomes, and imported into the organelle by processes discussed in Chapter 13.

In contrast to metazoan mtDNAs, plant mtDNAs are many times larger, and most of the DNA does not encode protein. For instance, the mtDNA in the important model plant *Arabidopsis thaliana* is 366,924 base pairs, and the largest known mtDNA is ≈ 2 Mb, found in cucurbit plants (e.g., melon and cucumber). Most plant mtDNA consists of long introns, pseudogenes, mobile DNA elements restricted to the mitochondrial compartment, and pieces of foreign (chloroplast, nuclear, and viral) DNA that were probably inserted into plant mitochondrial genomes during their evolution. Duplicated sequences also contribute to the greater length of plant mtDNAs.

Differences in the number of genes encoded by the mtDNA from various organisms most likely reflect the movement of DNA between mitochondria and the nucleus during evolution. Direct evidence for this movement comes from the observation that several proteins encoded by mtDNA

Lipid metabolism	Carbohydrate metabolism	Ubiquinone synthesis	Chaperones
Nucleotide metabolism	Heme synthesis	Co-factor synthesis	Signaling pathways
Amino acid metabolism	Fe-S synthesis	Proteases	DNA repair, replication, etc.

FIGURE 6-23 Proteins encoded in mitochondrial DNA and their involvement in mitochondrial processes. Only the mitochondrial matrix and inner membrane are depicted. Most mitochondrial components are encoded by the nucleus (blue); those highlighted in pink are encoded by mtDNA in some eukaryotes but by the nuclear genome in other eukaryotes, whereas a small portion are invariably specified by mtDNA (orange). Mitochondrial processes that have exclusively nucleus-encoded components are listed at the top. Complexes I–V are involved in electron transport and oxidative phosphorylation. TIM, Sec, Tat, and Oxa1 translocases are involved in

protein import and export, and insertion of proteins into the inner membrane (see Chapter 13). RNase P is a ribozyme that processes the 5' end of tRNAs (discussed in Chapter 8). It should be noted that the majority of eukaryotes have a multisubunit Complex I as depicted, with three subunits invariably encoded by mtDNA. However, in a few organisms (*Saccharomyces*, *Schizosaccharomyces*, and *Plasmodium*), this complex is replaced by a nucleus-encoded, single-polypeptide enzyme. For more details on mitochondrial metabolism and transport, see Chapters 12 and 13. [Adapted from G. Burger et al., 2003, *Trends Genet.* 19:709.]

in some species are encoded by nuclear DNA in other, closely related species. The most striking example of this phenomenon involves the *cox II* gene, which encodes subunit 2 of cytochrome *c* oxidase, which constitutes complex IV in the mitochondrial electron-transport chain (see Figure 12-16). This gene is found in mtDNA in all multicellular plants studied except for certain related species of legumes, including the mung bean and the soybean, in which the *cox II* gene is nuclear. The *cox II* gene is completely missing from mung bean mtDNA, but a defective *cox II* pseudogene that has accumulated many mutations can still be recognized in soybean mtDNA.

Many RNA transcripts of plant mitochondrial genes are edited, mainly by the enzyme-catalyzed conversion of selected C residues to U, and occasionally U to C. (RNA editing is discussed in Chapter 8.) The nuclear *cox II* gene of mung bean corresponds more closely to the edited *cox II* RNA transcripts than to the mitochondrial *cox II* genes found in other legumes. These observations are strong evidence that the *cox II* gene moved from the mitochondrion to the nucleus during mung bean evolution by a process that involved an RNA intermediate. Presumably this movement involved a reverse-transcription mechanism similar to that

by which processed pseudogenes are generated in the nuclear genome from nucleus-encoded mRNAs.

In addition to the large differences in the sizes of mtDNAs in different eukaryotes, the structure of the mtDNA also varies greatly. As mentioned above, mtDNA in most animals is a circular molecule ≈ 16 kb. However, the mtDNA of many organisms such as the protist *Tetrahymena* exists as linear head-to-tail concatemers of repeating sequence. In the most extreme examples, the mtDNA of the protist *Amoebidium parasiticum* is composed of several hundred distinct short linear molecules. And the mtDNA of *Trypanosoma* is comprised of multiple *maxicircles* concatenated (interlocked) to thousands of *minicircles* encoding *guide RNAs* involved in editing the sequence of the mitochondrial mRNAs encoded in the maxicircles.

Products of Mitochondrial Genes Are Not Exported

As far as is known, all RNA transcripts of mtDNA and their translation products remain in the mitochondrion in which they are produced, and all mtDNA-encoded proteins are synthesized on mitochondrial ribosomes. Mitochondrial

DNA encodes the rRNAs that form mitochondrial ribosomes, although most of the ribosomal proteins are imported from the cytosol. In animals and fungi, all the tRNAs used for protein synthesis in mitochondria also are encoded by mtDNAs. However, in plants and many protozoans, most mitochondrial tRNAs are encoded by the nuclear DNA and imported into the mitochondrion.

 Reflecting the bacterial ancestry of mitochondria, mitochondrial ribosomes resemble bacterial ribosomes and differ from eukaryotic cytosolic ribosomes in their RNA and protein compositions, their size, and their sensitivity to certain antibiotics (see Figure 4-22). For instance, chloramphenicol blocks protein synthesis by bacterial and mitochondrial ribosomes from most organisms, but cycloheximide, which inhibits protein synthesis on eukaryotic cytosolic ribosomes, does not affect mitochondrial ribosomes. This sensitivity of mitochondrial ribosomes to the important aminoglycoside class of antibiotics that includes chloramphenicol is the main cause of the toxicity that these antibiotics can cause. ■

Mitochondria Evolved from a Single Endosymbiotic Event Involving a *Rickettsia*-like Bacterium

Analysis of the mtDNA sequences from various eukaryotes, including single-celled protists that diverged from other eukaryotes early in evolution, provides strong support for the idea that the mitochondrion had a single origin. Mitochondria most likely arose from a bacterial symbiote whose closest contemporary relatives are in the *Rickettsiaceae* group. Bacteria in this group are obligate intracellular parasites. Thus, the ancestor of the mitochondrion probably also had an intracellular lifestyle, putting it in a good location for

evolving into an intracellular symbiote. The mtDNA with the largest number of encoded genes so far found is in the protist species *Reclinomonas americana*. All other mtDNAs have a subset of the *R. americana* genes, strongly implying that they evolved from a common ancestor with *R. americana*, losing different groups of mitochondrial genes by deletion and/or transfer to the nucleus over time.

In organisms whose mtDNA includes only a limited number of genes, the same set of mitochondrial genes is retained, independent of the phyla that include these organisms (see Figure 6-23, orange proteins). One hypothesis for why these genes were never successfully transferred to the nuclear genome is that their encoded polypeptides are too hydrophobic to cross the outer mitochondrial membrane, and therefore would not be imported back into the mitochondria if they were synthesized in the cytosol. Similarly, the large size of rRNAs may interfere with their transport from the nucleus through the cytosol into mitochondria. Alternatively, these genes may not have been transferred to the nucleus during evolution because regulation of their expression in response to conditions within individual mitochondria may be advantageous. If these genes were located in the nucleus, conditions within each mitochondrion could not influence the expression of proteins found in that mitochondrion.

Mitochondrial Genetic Codes Differ from the Standard Nuclear Code

The genetic code used in animal and fungal mitochondria is different from the standard code used in all prokaryotic and eukaryotic nuclear genes; remarkably, the code even differs in mitochondria from different species (Table 6-3). Why and how these differences arose during evolution is mysterious. UGA, for example, is normally a stop codon, but is read as tryptophan by human and fungal mitochondrial translation

TABLE 6-3 Alterations in the Standard Genetic Code in Mitochondria

Codon	Standard Code *	Mitochondria				
		Mammals	<i>Drosophila</i>	<i>Neurospora</i>	Yeasts	Plants
UGA	Stop	Trp	Trp	Trp	Trp	Stop
AGA, AGG	Arg	Stop	Ser	Arg	Arg	Arg
AUA	Ile	Met	Met	Ile	Met	Ile
AUU	Ile	Met	Met	Met	Met	Ile
CUU, CUC, CUA, CUG	Leu	Leu	Leu	Leu	Thr	Leu

Covello and M. W. Gray, 1989, *Nature* 341:662-666.

systems; however, in plant mitochondria, UGA is still recognized as a stop codon. AGA and AGG, the standard nuclear codons for arginine, also code for arginine in fungal and plant mtDNA, but they are stop codons in mammalian mtDNA and serine codons in *Drosophila* mtDNA.

As shown in Table 6-3, plant mitochondria appear to utilize the standard genetic code. However, comparisons of the amino acid sequences of plant mitochondrial proteins with the nucleotide sequences of plant mtDNAs suggested that CGG could code for *either* arginine (the “standard” amino acid) or tryptophan. This apparent nonspecificity of the plant mitochondrial code is explained by editing of mitochondrial RNA transcripts, which can convert cytosine residues to uracil residues. If a CGG sequence is edited to UGG, the codon specifies tryptophan, the standard amino acid for UGG, whereas unedited CGG codons encode the standard arginine. Thus the translation system in plant mitochondria does utilize the standard genetic code. ■

Mutations in Mitochondrial DNA Cause Several Genetic Diseases in Humans

The severity of disease caused by a mutation in mtDNA depends on the nature of the mutation and on the proportion of mutant and wild-type mtDNAs present in a particular cell type. Generally, when mutations in mtDNA are found, cells contain mixtures of wild-type and mutant mtDNAs—a condition known as *heteroplasmy*. Each time a mammalian somatic or germ-line cell divides, the mutant and wild-type mtDNAs segregate randomly into the daughter cells, as occurs in yeast cells (see Figure 6-22b). Thus, the mtDNA genotype, which fluctuates from one generation and from one cell division to the next, can drift toward predominantly wild-type or predominantly mutant mtDNAs. Since all enzymes required for the replication and growth of mammalian mitochondria, such as the mitochondrial DNA and RNA polymerases, are encoded in the nucleus and imported from the cytosol, a mutant mtDNA should not be at a “replication disadvantage”; mutants that involve large deletions of mtDNA might even be at a selective advantage in replication, because they can replicate faster.

Recent research suggests that the accumulation of mutations in mtDNA is an important component of aging in mammals. Mutations in mtDNA have been observed to accumulate with aging, probably because mammalian mtDNA is not repaired in response to DNA damage. To study this hypothesis, researchers used gene “knock-in” techniques to replace the nuclear gene encoding mitochondrial DNA polymerase with normal proofreading activity (see Figure 4-34) with a mutant gene encoding a polymerase defective in proofreading. Mutations in mtDNA accumulated much more rapidly in homozygous mutant mice than in wild-type mice, and the mutant mice aged at a highly accelerated rate (Figure 6-24).

With few exceptions, all human cells have mitochondria, yet mutations in mtDNA affect only some tissues. Those most commonly affected are tissues that have a high

EXPERIMENTAL FIGURE 6-24 Mice with a mitochondrial DNA polymerase defective for proofreading exhibit premature aging.

A line of “knock-in” mice were prepared by methods discussed in Chapter 5 with an aspartic acid-to-alanine mutation in the gene encoding mitochondrial DNA polymerase (D257A), inactivating the polymerase’s proofreading function. (a) Wild-type and homozygous mutant mice at 390 days old (13 months). The mutant mouse displays many of the features of an aged mouse (>720 days, or 24 months of age). (b) Plot of survival versus time of wild-type (+/+), heterozygous (D257A/+) and homozygous (D257A/D257A) mice. [From G. C. Kujoth et al., 2005, *Science* 309:481. Part (a) courtesy of Jeff Miller/University of Wisconsin-Madison and Gregory Kujoth, Ph.D.]

requirement for ATP produced by oxidative phosphorylation and tissues that require most or all of the mtDNA in the cell to synthesize sufficient amounts of functional mitochondrial proteins. For instance, *Leber’s hereditary optic neuropathy* (degeneration of the optic nerve) is caused by a missense mutation in the mtDNA gene encoding subunit 4 of the NADH-CoQ reductase (complex I), a protein required for ATP production by mitochondria (see Figure 12-16). Any of several large deletions in mtDNA causes another set of diseases, including *chronic progressive external ophthalmoplegia*, characterized by eye defects, and *Kearns-Sayre syndrome*, characterized by eye defects, abnormal heartbeat, and central nervous system degeneration. A third condition, causing “ragged” muscle fibers (with improperly assembled mitochondria) and associated uncontrolled jerky movements, is due to a single mutation in the TΨCG loop of the mitochondrial lysine tRNA. As a result of this mutation, the translation of several mitochondrial proteins apparently is inhibited. ■

Chloroplasts Contain Large DNAs Often Encoding More Than a Hundred Proteins

Like mitochondria, chloroplasts are thought to have evolved from an ancestral endosymbiotic photosynthetic bacterium (see Figure 6-20). However, the endosymbiotic event giving rise to chloroplasts occurred more recently (1.2–1.5 billion years ago) than the event leading to the evolution of mitochondria (1.5–2.2 billion years ago). Consequently, contemporary chloroplast DNAs show less structural diversity than do mtDNAs. Also similar to mitochondria, chloroplasts contain multiple copies of the organellar DNA and ribosomes, which synthesize some chloroplast-encoded proteins using the standard genetic code. Like plant mtDNA, chloroplast DNA is inherited exclusively in a uniparental fashion through the female parent (egg). Other chloroplast proteins are encoded by nuclear genes, synthesized on cytosolic ribosomes, and then incorporated into the organelle (Chapter 13). ■

In higher plants, chloroplast DNAs are 120–160 kb long, depending on the species. They initially were thought to be circular DNA molecules because in genetically tractable organisms such as the model plant protozoan *Chlamydomonas reinhardtii*, the genetic map is circular. However, recent studies have revealed that plant chloroplast DNAs are actually long head-to-tail linear concatemers plus recombination intermediates between these long linear molecules. In these studies, researchers have used techniques that minimize mechanical breakage of long DNA molecules during isolation and gel electrophoresis, permitting analysis of megabase-size DNA.

The complete sequences of several chloroplast DNAs from higher plants have been determined. They contain 120–135 genes, 130 in the important model plant *Arabidopsis thaliana*. *A. thaliana* chloroplast DNA encodes 76 protein-coding genes and 54 genes with RNA products such as rRNAs and tRNAs. Chloroplast DNAs encode the subunits of a bacterial-like RNA polymerase and express many of their genes from polycistronic operons as in bacteria (see Figure 4-13a). Some chloroplast genes contain introns, but these are similar to the specialized introns found in some bacterial genes and in mitochondrial genes from fungi and protozoans, rather than the introns of nuclear genes. As in the evolution of mitochondrial genomes, many genes in the ancestral chloroplast endosymbiote that were redundant with nuclear genes have been lost from chloroplast DNA. Also, many genes essential for chloroplast function have been transferred to the nuclear genome of plants over evolutionary time. Recent estimates from sequence analysis of the *A. thaliana* and cyanobacterial genomes indicate that ≈4500 genes have been transferred from the original endosymbiote to the nuclear genome.

Methods similar to those used for the transformation of yeast cells (Chapter 5) have been developed for stably introducing foreign DNA into the chloroplasts of higher

plants. The large number of chloroplast DNA molecules per cell permits the introduction of thousands of copies of an engineered gene into each cell, resulting in extraordinarily high levels of foreign protein production. Chloroplast transformation has recently led to the engineering of plants that are resistant to bacterial and fungal infections, drought, and herbicides. The level of production of foreign proteins is comparable with that achieved with engineered bacteria, making it likely that chloroplast transformation will be used for the production of human pharmaceuticals and possibly for the engineering of food crops containing high levels of all the amino acids essential to humans. ■

KEY CONCEPTS of Section 6.4

Organelle DNAs

- Mitochondria and chloroplasts most likely evolved from bacteria that formed a symbiotic relationship with ancestral cells containing a eukaryotic nucleus (see Figure 6-20).
- Most of the genes originally within mitochondria and chloroplasts were either lost because their functions were redundant with nuclear genes or moved to the nuclear genome over evolutionary time, leaving different gene sets in the organellar DNAs of different organisms (see Figure 6-23).
- Animal mtDNAs are circular molecules, reflecting their probable bacterial origin. Plant mtDNAs and chloroplast DNAs generally are longer than mtDNAs from other eukaryotes, largely because they contain more noncoding regions and repetitive sequences.
- All mtDNAs and chloroplast DNAs encode rRNAs and some of the proteins involved in mitochondrial or photosynthetic electron transport and ATP synthesis. Most animal mtDNAs and chloroplast DNAs also encode the tRNAs necessary to translate the organellar mRNAs.
- Because most mtDNA is inherited from egg cells rather than sperm, mutations in mtDNA exhibit a maternal cytoplasmic pattern of inheritance. Similarly, chloroplast DNA is exclusively inherited from the maternal parent.
- Mitochondrial ribosomes resemble bacterial ribosomes in their structure, sensitivity to chloramphenicol, and resistance to cycloheximide.
- The genetic code of animal and fungal mtDNAs differs slightly from that of bacteria and the nuclear genome and varies among different animals and fungi (see Table 6-3). In contrast, plant mtDNAs and chloroplast DNAs appear to conform to the standard genetic code.
- Several human neuromuscular disorders result from mutations in mtDNA. Patients generally have a mixture of wild-type and mutant mtDNA in their cells (heteroplasmy): the higher the fraction of mutant mtDNA, the more severe is the mutant phenotype.

6.5 Genomics: Genome-wide Analysis of Gene Structure and Expression

Using automated DNA sequencing techniques and computer algorithms to piece together the sequence data, researchers have determined vast amounts of DNA sequence including nearly the entire genomic sequence of humans and many key experimental organisms. This enormous volume of data, which is growing at a rapid pace, has been stored and organized in two primary data banks: the GenBank at the National Institutes of Health, Bethesda, Maryland, and the EMBL Sequence Data Base at the European Molecular Biology Laboratory in Heidelberg, Germany. These databases continuously exchange newly reported sequences and make them available to scientists throughout the world on the Internet. By now, the genome sequences have been completely, or nearly completely, determined for hundreds of viruses and bacteria, scores of archaea, yeasts (eukaryotes), plants including rice and maize, important model multicellular eukaryotes such as the roundworm *C. elegans*, the fruit fly *Drosophila melanogaster*, mice, humans, and representatives of the ≈ 35 metazoan phyla. The cost and speed of sequencing a megabase of DNA has fallen so low that the entire genome in cancer cells has been sequenced and compared to the genome in normal cells from the same patient in order to determine all the mutations that have accumulated in that patient's tumor cells. This approach may reveal genes that are commonly mutated in all cancers, as well as genes that are commonly mutated in tumor cells from different patients with the same type of cancer (e.g., breast versus colon cancer). This approach may eventually lead to highly individualized cancer treatments tailored to the specific mutations in the tumor cells of a particular patient. The latest automated DNA sequencing techniques are so powerful that a project known as the "1000 Genomes Project" is currently underway with the goal of sequencing most of the genomes of 1000–2000 randomly chosen individuals from all over the world in order to determine the extent of human genetic variation as a basis for investigating the relationship between genotype and phenotype in humans. Moreover, privately owned companies have been founded that will sequence much of an individual's genome for $\approx \$100$ in order to search for sequence variations that may influence the probability of developing specific diseases.

In this section, we examine some of the ways researchers are mining this treasure trove of data to provide insights about gene function and evolutionary relationships, to identify new genes whose encoded proteins have never been isolated, and to determine when and where genes are expressed. This use of computers to analyze sequence data has led to the emergence of a new field of biology: *bioinformatics*.

Stored Sequences Suggest Functions of Newly Identified Genes and Proteins

As discussed in Chapter 3, proteins with similar functions often contain similar amino acid sequences that correspond to important functional domains in the three-dimensional

structure of the proteins. By comparing the amino acid sequence of the protein encoded by a newly cloned gene with the sequences of proteins of known function, an investigator can look for sequence similarities that provide clues to the function of the encoded protein. Because of the degeneracy in the genetic code, related proteins invariably exhibit more sequence similarity than the genes encoding them. For this reason, protein sequences rather than the corresponding DNA sequences are usually compared.

The most widely used computer program for this purpose is known as BLAST (*basic local alignment search tool*). The BLAST algorithm divides the "new" protein sequence (known as the *query sequence*) into shorter segments and then searches the database for significant matches to any of the stored sequences. The matching program assigns a high score to identically matched amino acids and a lower score to matches between amino acids that are related (e.g., hydrophobic, polar, positively charged, negatively charged) but not identical. When a significant match is found for a segment, the BLAST algorithm will search locally to extend the region of similarity. After searching is completed, the program ranks the matches between the query protein and various known proteins according to their *p-values*. This parameter is a measure of the probability of finding such a degree of similarity between two protein sequences by chance. The lower the *p-value*, the greater is the sequence similarity between two sequences. A *p-value* less than about 10^{-3} usually is considered as significant evidence that two proteins share a common ancestor. Many alternative computer programs have been developed in addition to BLAST that can detect relationships between proteins that are more distantly related to each other than can be detected by BLAST. The development of such methods is currently an active area of bioinformatics research.

To illustrate the power of this approach, we consider the human gene *NF1*. Mutations in *NF1* are associated with the inherited disease neurofibromatosis 1, in which multiple tumors develop in the peripheral nervous system, causing large protuberances in the skin. After a cDNA clone of *NF1* was isolated and sequenced, the deduced sequence of the NF1 protein was checked against all other protein sequences in GenBank. A region of NF1 protein was discovered to have considerable homology to a portion of the yeast protein called Ira (Figure 6-25). Previous studies had shown that Ira is a GTPase-activating protein (GAP) that modulates the GTPase activity of the monomeric G protein called Ras (see Figure 3-32). As we examine in detail in Chapter 16, GAP and Ras proteins normally function to control cell replication and differentiation in response to signals from neighboring cells. Functional studies on the normal NF1 protein, obtained by expression of the cloned wild-type gene, showed that it did, indeed, regulate Ras activity, as suggested by its homology with Ira. These findings suggest that patients with neurofibromatosis express a mutant NF1 protein in cells of the peripheral nervous system, leading to inappropriate cell division and formation of the tumors characteristic of the disease. ■

FIGURE 6-25 Comparison of the regions of human NF1 protein and *S. cerevisiae* Ira protein that show significant sequence similarity. The NF1 and the Ira sequences are shown on the top and bottom lines of each row, respectively, in the one-letter amino acid code (see Figure 2-14). Amino acids that are identical in the two proteins are highlighted in yellow. Amino acids with chemically similar

but nonidentical side chains are connected by a blue dot. Amino acid numbers in the protein sequences are shown at the left and right ends of each row. Black dots indicate "gaps" in the protein sequence inserted in order to maximize the alignment of homologous amino acids. The BLAST *p*-value for these two sequences is 10^{-28} , indicating a high degree of similarity. [From G. Xu et al., 1990, *Cell* 62:599.]

Even when a protein shows no significant similarity to other proteins with the BLAST algorithm, it may nevertheless share a short sequence that is functionally important. Such short segments recurring in many different proteins, referred to as **structural motifs**, generally have similar functions. Several such motifs are described in Chapter 3 and illustrated in Figure 3-9. To search for these and other motifs in a new protein, researchers compare the query protein sequence with a database of known motif sequences.

Comparison of Related Sequences from Different Species Can Give Clues to Evolutionary Relationships Among Proteins

BLAST searches for related protein sequences may reveal that proteins belong to a protein family. Earlier, we considered gene families in a single organism, using the β -globin genes in humans as an example (see Figure 6-4a). But in a database that includes the genome sequences of multiple organisms, protein families also can be recognized as being shared among related organisms. Consider, for example, the **tubulin** proteins; these are the basic subunits of microtubules, which are important components of the cytoskeleton (Chapter 18). According to the simplified scheme in Figure 6-26a, the earliest eukaryotic cells are thought to have contained a single tubulin gene that was duplicated early in evolution; subsequent divergence of the different copies of the original tubulin gene formed the ancestral versions of the α - and β -tubulin genes. As different species diverged from these early eukaryotic cells, each of these gene sequences further diverged, giving rise to the slightly different forms of α -tubulin and β -tubulin now found in each species.

All the different members of the tubulin family of genes (or proteins) are sufficiently similar in sequence to suggest a common ancestral sequence. Thus all these sequences are considered to be *homologous*. More specifically, sequences that presumably diverged as a result of gene duplication (e.g., the α - and β -tubulin sequences) are described as *paralogous*. Sequences that arose because of speciation (e.g., the α -tubulin genes in different species) are described as *orthologous*. From the degree of sequence relatedness of the tubulins present in different organisms today, evolutionary relationships can be deduced, as illustrated in Figure 6-26b. Of the three types of sequence relationships, orthologous sequences are the most likely to share the same function.

Genes Can Be Identified Within Genomic DNA Sequences

The complete genomic sequence of an organism contains within it the information needed to deduce the sequence of every protein made by the cells of that organism. For organisms such as bacteria and yeast, whose genomes have few introns and short intergenic regions, most protein-coding sequences can be found simply by scanning the genomic sequence for **open reading frames (ORFs)** of significant length. An ORF usually is defined as a stretch of DNA containing at least 100 codons that begins with a start codon and ends with a stop codon. Because the probability that a random DNA sequence will contain no stop codons for 100 codons in a row is very small, most ORFs encode protein.

ORF analysis correctly identifies more than 90 percent of the genes in yeast and bacteria. Some of the very shortest genes,

FIGURE 6-26 Generation of diverse tubulin sequences during the evolution of eukaryotes. (a) Probable mechanism giving rise to the tubulin genes found in existing species. It is possible to deduce that a gene duplication event occurred before speciation because the α -tubulin sequences from different species (e.g., humans and yeast) are more alike than are the α -tubulin and β -tubulin sequences within a species. (b) A phylogenetic tree representing the relationship between the tubulin sequences. The branch points (nodes), indicated by small numbers, represent common ancestral genes at the time that two

sequences diverged. For example, node 1 represents the duplication event that gave rise to the α -tubulin and β -tubulin families, and node 2 represents the divergence of yeast from multicellular species. Braces and arrows indicate, respectively, the orthologous tubulin genes, which differ as a result of speciation, and the paralogous genes, which differ as a result of gene duplication. This diagram is simplified somewhat because flies, worms, and humans actually contain multiple α -tubulin and β -tubulin genes that arose from later gene duplication events.

however, are missed by this method, and occasionally long open reading frames that are not actually genes arise by chance. Both types of mis-assignments can be corrected by more sophisticated analysis of the sequence and by genetic tests for gene function. Of the *Saccharomyces* genes identified in this manner, about half were already known by some functional criterion such as mutant phenotype. The functions of some of the proteins encoded by the remaining putative (suspected) genes identified by ORF analysis have been assigned based on their sequence similarity to known proteins in other organisms.

Identification of genes in organisms with a more complex genome structure requires more sophisticated algorithms than searching for open reading frames. Because most genes in higher eukaryotes are composed of multiple, relatively short exons separated by often quite long noncoding introns, scanning for ORFs is a poor method for finding genes. The best gene-finding algorithms combine all the available data that might suggest the presence of a gene at a particular genomic site. Relevant data include alignment or hybridization of the query sequence to a full-length cDNA; alignment to a partial cDNA sequence, generally 200–400 bp in length, known as an *expressed sequence tag* (EST); fitting to models for exon, intron, and splice site sequences; and sequence similarity to other organisms. Using these computer-based bioinformatic methods, computational biologists have identified approximately $\approx 19,800$ protein coding genes in the human genome.

A particularly powerful method for identifying human genes is to compare the human genomic sequence with that of the mouse. Humans and mice are sufficiently related to

have most genes in common, although largely nonfunctional DNA sequences, such as intergenic regions and introns, will tend to be very different because these sequences are not under strong selective pressure. Thus corresponding segments of the human and mouse genome that exhibit high sequence similarity are likely to be functionally important: exons, transcription-control regions, or sequences with other functions that are not yet understood.

The Number of Protein-Coding Genes in an Organism's Genome Is Not Directly Related to Its Biological Complexity

The combination of genomic sequencing and gene-finding computer algorithms has yielded the complete inventory of protein-coding genes for a variety of organisms. Figure 6-27 shows the total number of protein-coding genes in several eukaryotic genomes that have been completely sequenced. The functions of about half the proteins encoded in these genomes are known or have been predicted on the basis of sequence comparisons. One of the surprising features of this comparison is that the number of protein-coding genes within different organisms does not seem proportional to our intuitive sense of their biological complexity. For example, the roundworm *C. elegans* apparently has more genes than the fruit fly *Drosophila*, which has a much more complex body plan and more complex behavior. And humans have fewer than one and one-half the number of genes as *C. elegans*. When it first became apparent that humans have fewer than

FIGURE 6-27 Comparison of the number and types of proteins encoded in the genomes of different eukaryotes. For each organism, the area of the entire pie chart represents the total number of protein-coding genes, all shown at roughly the same scale. In most cases, the functions of the proteins encoded by about half the genes are still unknown (light blue). The functions of the remainder are known or have been predicted by sequence similarity to genes of known function. [Adapted from International Human Genome Sequencing Consortium, 2001, *Nature* 409:860.]

twice the number of protein-coding genes as the simple roundworm, it was difficult to understand how such a small increase in the number of proteins could generate such a staggering difference in complexity.

Clearly, simple quantitative differences in the number of genes in the genomes of different organisms are inadequate for explaining differences in biological complexity. However, several phenomena can generate more complexity in the expressed proteins of higher eukaryotes than is predicted from their genomes. First, alternative splicing of a pre-mRNA can yield multiple functional mRNAs corresponding to a particular gene (Chapter 8). Second, variations in the post-translational modification of some proteins may produce functional differences. Finally, increased biological complexity results from increased numbers of cells built of the same kinds of proteins. Larger numbers of cells can interact in more complex combinations, as in comparing the cerebral cortex from mouse to man. Similar cells are present in both the mouse and human cerebral cortex, but in humans more of them make more complex connections. Evolution of the increasing biological complexity of multicellular organisms likely required increasingly complex regulation of cell

replication and gene expression, leading to increasing complexity of embryological development.

The specific functions of many genes and proteins identified by analysis of genomic sequences still have not been determined. As researchers unravel the functions of individual proteins in different organisms and further detail their interactions with other proteins, the resulting advances will become immediately applicable to all homologous proteins in other organisms. When the function of every protein is known, no doubt, a more sophisticated understanding of the molecular basis of complex biological systems will emerge.

KEY CONCEPTS of Section 6.5

Genomics: Genome-wide Analysis of Gene Structure and Expression

- The function of a protein that has not been isolated (a query protein) often can be predicted on the basis of similarity of its amino acid sequence to the sequences of proteins of known function.

- A computer algorithm known as BLAST rapidly searches databases of known protein sequences to find those with significant similarity to a query protein.
- Proteins with common functional motifs, which often can be quite short, may not be identified in a typical BLAST search. Such short sequences may be located by searches of motif databases.
- A protein family comprises multiple proteins all derived from the same ancestral protein. The genes encoding these proteins, which constitute the corresponding gene family, arose by an initial gene duplication event and subsequent divergence during speciation (see Figure 6-26).
- Related genes and their encoded proteins that derive from a gene duplication event are paralogous, such as the α - and β -globins that combine in hemoglobin ($\alpha_2\beta_2$); those that derive from mutations that accumulated during speciation are orthologous. Proteins that are orthologous usually have a similar function in different organisms, such as the mouse and human adult β -globins.
- Open reading frames (ORFs) are regions of genomic DNA containing at least 100 codons located between a start codon and stop codon.
- Computer search of the entire bacterial and yeast genomic sequences for open reading frames (ORFs) correctly identifies most protein-coding genes. Several types of additional data must be used to identify probable (putative) genes in the genomic sequences of humans and other higher eukaryotes because of their more complex gene structure, in which relatively short coding exons are separated by relatively long, noncoding introns.
- Analysis of the complete genome sequences for several different organisms indicates that biological complexity is not directly related to the number of protein-coding genes (see Figure 6-27).

6.6 Structural Organization of Eukaryotic Chromosomes

Now that we have examined the various types of DNA sequences found in eukaryotic genomes and how they are organized within it, we turn to the question of how DNA molecules as a whole are organized within eukaryotic cells. Because the total length of cellular DNA is up to a hundred thousand times a cell's diameter, the packing of DNA is crucial to cell architecture. It is also essential to prevent the long DNA molecules from getting knotted or tangled with each other during cell division, when they must be precisely segregated to daughter cells. The task of compacting and organizing chromosomal DNA is performed by abundant nuclear proteins called **histones**. The complex of histones and DNA is called **chromatin**.

Chromatin, which is about half DNA and half protein by mass, is dispersed throughout much of the nucleus in inter-

phase cells (those that are not undergoing mitosis). Further folding and compaction of chromatin during mitosis produces the visible *metaphase chromosomes*, whose morphology and staining characteristics were detailed by early cytogeneticists. Although every eukaryotic chromosome includes millions of individual protein molecules, each chromosome contains just one, extremely long, linear DNA molecule. The longest DNA molecules in human chromosomes, for instance, are 2.8×10^8 base pairs, or almost 10 cm, in length! The structural organization of chromatin allows this vast length of DNA to be compacted into the microscopic constraints of a cell nucleus (see Figure 6-1). Yet chromatin is organized in such a way that specific DNA sequences within the chromatin are readily available for cellular processes such as the transcription, replication, repair, and recombination of DNA molecules. In this section, we consider the properties of chromatin and its organization into chromosomes. Important features of chromosomes in their entirety are covered in the next section.

Chromatin Exists in Extended and Condensed Forms

When the DNA from eukaryotic nuclei is isolated using a method that preserves native protein–DNA interactions, it is associated with an equal mass of protein in the nucleoprotein complex known as chromatin. Histones, the most abundant proteins in chromatin, constitute a family of small, basic proteins. The five major types of histone proteins—termed *H1*, *H2A*, *H2B*, *H3*, and *H4*—are rich in positively charged basic amino acids, which interact with the negatively charged phosphate groups in DNA.

When chromatin is extracted from nuclei and examined in the electron microscope, its appearance depends on the salt concentration to which it is exposed. At low salt concentration in the absence of divalent cations such as Mg^{+2} , isolated chromatin resembles “beads on a string” (Figure 6-28a). In this extended form, the string is composed of free DNA called “linker” DNA connecting beadlike structures termed **nucleosomes**. Composed of DNA and histones, nucleosomes are about 10 nm in diameter and are the primary structural units of chromatin. If chromatin is isolated at physiological salt concentration, it assumes a more condensed fiberlike form that is 30 nm in diameter (Figure 6-28b).

Structure of Nucleosomes The DNA component of nucleosomes is much less susceptible to nuclease digestion than is the linker DNA between them. If nuclease treatment is carefully controlled, all the linker DNA can be digested, releasing individual nucleosomes with their DNA component. A nucleosome consists of a protein core with DNA wound around its surface like thread around a spool. The core is an octamer containing two copies each of histones *H2A*, *H2B*, *H3*, and *H4*. X-ray crystallography has shown that the octameric histone core is a roughly disk-shaped structure made of interlocking histone subunits (Figure 6-29). Nucleosomes from all eukaryotes contain ≈ 147 base pairs of DNA wrapped one

EXPERIMENTAL FIGURE 6-28 The extended and condensed forms of extracted chromatin have very different appearances in electron micrographs. (a) Chromatin isolated in low-ionic-strength buffer has an extended “beads-on-a-string” appearance. The “beads” are nucleosomes (10-nm diameter) and the “string” is connecting (linker) DNA. (b) Chromatin isolated in buffer with a physiological ionic strength (0.15 M KCl) appears as a condensed fiber 30 nm in diameter. [Part (a) courtesy of S. McKnight and O. Miller, Jr. Part (b) courtesy of B. Hamkalo and J. B. Rattner.]

and two-thirds turns around the protein core. The length of the linker DNA is more variable among species, and even between different cells of one organism, ranging from about 10 to 90 base pairs. During cell replication, DNA is assembled into nucleosomes shortly after the replication fork passes (see Figure 4-33). This process depends on specific histone chaperones that bind to histones and assemble them together with newly replicated DNA into nucleosomes.

Structure of the 30-nm Fiber When extracted from cells in isotonic buffers (i.e., buffers with the same salt concentration found in cells, ≈ 0.15 M KCl, 0.004 M MgCl_2), most chromatin appears as fibers ≈ 30 nm in diameter (see Figure 6-28b). Current research, including x-ray crystallography of

nucleosomes assembled from recombinant histones, indicates that the 30-nm fiber has a “zig-zag ribbon” structure that is wound into a “two-start” helix made from two “strands” of nucleosomes stacked on top of each other like coins. The two “strands” of stacked nucleosomes are then wound into a double helix similarly to the two strands in a DNA double helix, except that the helix is left handed, rather than right handed as it is in DNA (Figure 6-30). The 30-nm fibers also include H1, the fifth major histone. H1 is bound to the DNA as it enters and exits the nucleosome core, but its structure in the 30-nm fiber is not known at atomic resolution.

The chromatin in chromosomal regions that are not being transcribed or replicated exists predominantly in the condensed, 30-nm fiber form and in higher-order folded structures

FIGURE 6-29 Structure of the nucleosome based on x-ray crystallography. (a) Nucleosome with space-filling model of the histones. The sugar-phosphate backbones of the DNA strands are represented as white tubes to allow better visualization of the histones. Nucleosome shown from the top (left) and from the side (right, rotated clockwise 90°). H2A subunits are yellow; H2Bs are red; H3s are blue; H4s

are green. The N-terminal tails of the eight histones and the H2A and H2B C-terminal tails, involved in condensation of the chromatin, are not visible because they are disordered in the crystal. (b) Space-filling model of histones and DNA (white) viewed from the side of the nucleosome. [Parts (a) and (b) after K. Luger et al., 1997, *Nature* 389:251.]

whose detailed conformation is not currently understood. The regions of chromatin actively being transcribed are thought to assume the extended beads-on-a-string form.

Conservation of Chromatin Structure The general structure of chromatin is remarkably similar in the cells of all eukaryotes, including fungi, plants, and animals, indicating that the structure of chromatin was optimized early in the evolution of eukaryotic cells. The amino acid sequences for four histones (H2A, H2B, H3, and H4) are highly conserved between distantly related species. For example, the sequences of histone H3 from sea urchin tissue and calf thymus differ by only a single amino acid, and H3 from the garden pea and calf thymus differ only in four amino acids. Apparently, significant deviations from the histone amino acid sequences were selected against strongly during evolution. The amino acid sequence of H1, however, varies more from organism to organism than do the sequences of the other major histones. The similarity in sequence among histones from all eukaryotes suggests that they fold into very similar three-dimensional conformations, which were optimized for histone function early in evolution in a common ancestor of all modern eukaryotes.

Minor histone variants encoded by genes that differ from the highly conserved major types also exist, particularly in vertebrates. For example, a special form of H2A, designated H2AX, is incorporated into nucleosomes in place of H2A in a small fraction of nucleosomes in all regions of chromatin. At sites of DNA double-stranded breaks in chromosomal DNA, H2AX becomes phosphorylated and participates in the chromosome-repair process, probably by functioning as a binding site for repair proteins. In the nucleosomes at centromeres, H3 is replaced by another variant histone called CENP-A, which participates in the binding of spindle microtubules during mitosis. Most minor histone variants differ only slightly in sequence from the major histones. These slight changes in histone sequence may influence the stability of the nucleosome as well as its tendency to fold into the 30-nm fiber and other higher-order structures.

Modifications of Histone Tails Control Chromatin Condensation and Function

Each of the histone proteins making up the nucleosome core contains a flexible N-terminus of 19–39 residues extending from the globular structure of the nucleosome; the H2A and H2B proteins also contain a flexible C-terminus extending from the globular histone octamer core. These termini, called *histone tails*, are represented in the model shown in Figure 6-31a. The histone tails are required for chromatin to condense from the beads-on-a-string conformation into the 30-nm fiber. For example, recent experiments indicate that the N-terminal tails of histone H4, particularly lysine16, are critical for forming the 30-nm fiber. This positively charged lysine interacts with a negative patch at the H2A–H2B interface of the next nucleosome in the stacked nucleosomes of the 30-nm fiber (see Figure 6-30).

FIGURE 6-30 Structure of the 30-nm chromatin fiber. (a) Model for the folding of a nucleosomal chain at top into a "zig-zag ribbon" of nucleosomes that then folds into a two-start helix at bottom. For simplicity, DNA is not represented in the two-start helix. (b) Model of the 30-nm fiber based on x-ray crystallography of a tetranucleosome (a short stretch of four nucleosomes). [Part (a) adapted from C. L. F. Woodcock et al., 1984, *J. Cell Biol.* **99**:42. Part (b) from T. Schalch et al., 2005, *Nature* **436**:138.]

Histone tails are subject to multiple post-translational modifications such as acetylation, methylation, phosphorylation, and ubiquitination. Figure 6-31b summarizes the types of post-translational modifications observed in human histones. A particular histone protein never has all of these modifications simultaneously, but the histones in a single nucleosome usually contain several of these modifications simultaneously. The particular combinations of post-transcriptional modifications found in different regions of chromatin have been suggested to constitute a *histone code* that influences chromatin function by creating or removing binding sites for

FIGURE 6-31 Post-translational modifications observed on human histones. (a) Model of a nucleosome viewed from the top with histones shown as ribbon diagrams. This model depicts the lengths of the histone tails (dotted lines), which are not visible in the crystal structure (see Figure 6-29). The H2A N-terminal tails are at the bottom, and the H2A C-terminal tails are at the top. The H2B N-terminal tails are on the right and left, and C-terminal tails are at the bottom center. Histones H3 and H4 have short C-terminal tails that are not modified.

(b) Summary of post-translational modifications observed in human histones. Histone-tail sequences are shown in the one-letter amino acid code (see Figure 2-14). The main portion of each histone is depicted as an oval. These modifications do not all occur simultaneously on a single histone molecule. Rather, specific combinations of a few these modifications are observed on any one histone. [Part (a) from K. Luger and T. J. Richmond, 1998, *Curr. Opin. Genet. Devel.* 8:140. Part (b) adapted from R. Margueron et al., 2005, *Curr. Opin. Genet. Devel.* 15:163.]

chromatin-associated proteins dependent on the specific combinations of these modifications present. Here we describe the most abundant kinds of modifications found in histone tails and how these modifications control chromatin condensation and function. We end with a discussion of a special case of chromatin condensation, the inactivation of X chromosomes in female mammals.

Histone Acetylation Histone-tail lysines undergo reversible acetylation and deacetylation by enzymes that act on specific lysines in the N-termini. In the acetylated form, the positive charge of the lysine ϵ -amino group is neutralized. As mentioned above, lysine 16 in histone H4 is particularly important for the folding of the 30-nm fiber because it interacts with a negatively charged patch on the surface of the neighboring nucleosome in the fiber. Consequently, when H4 lysine 16 is acetylated, the chromatin tends to form the less condensed "beads-on-a-string" conformation conducive for transcription and replication.

Histone acetylation at other sites in H4 and in other histones (see Figure 6-31a) is correlated with increased sensitivity of chromatin DNA to digestion by nucleases. This phenomenon can be demonstrated by digesting isolated nuclei with DNase I. Following digestion, the DNA is completely separated

from chromatin protein, digested to completion with a restriction enzyme, and analyzed by Southern blotting. An intact gene treated with a restriction enzyme yields fragments of characteristic sizes. If isolated nuclei are exposed first to DNase, the gene may be cleaved at random sites within the boundaries of the restriction enzyme cut sites. Consequently, any Southern blot bands normally seen with that gene will be lost. This method was first used to show that the transcriptionally inactive β -globin gene in nonerythroid cells, where it is associated with relatively unacetylated histones, is much more resistant to DNase I than is the active, transcribed β -globin gene in erythroid precursor cells, where it is associated with acetylated histones (Figure 6-32). These results indicate that the chromatin structure of nontranscribed DNA in *hypoacetylated* chromatin makes the DNA less accessible to the small DNase I enzyme (≈ 10 kD) than it is in transcribed, *hyperacetylated* chromatin. This is thought to be because chromatin containing the repressed gene is folded into condensed structures that sterically inhibit access of the associated DNA to the nuclease. In contrast, the transcribed gene is associated with a more unfolded form of chromatin that allows better access of the nuclease to the associated DNA. Presumably, the condensed chromatin structure in nonerythroid cells also sterically inhibits access of the promoter

EXPERIMENTAL FIGURE 6-32 Nontranscribed genes are less susceptible to DNase I digestion than active genes. Chick embryo erythroblasts at 14 days actively synthesize globin, whereas undifferentiated chicken lymphoblastic leukemia (MSB) cells do not. (a) Nuclei from each type of cell were isolated and exposed to increasing concentrations of DNase I. The nuclear DNA was then extracted and treated with the restriction enzyme *Bam*HI, which cleaves the DNA around the globin sequence and normally releases a 4.6-kb globin fragment. (b) The DNase I- and *Bam*HI-digested DNA was subjected to Southern blot analysis with a probe of labeled cloned adult globin DNA, which hybridizes to the 4.6-kb *Bam*HI fragment. If the globin gene is susceptible to the initial DNase digestion, it would be cleaved repeatedly and would not be expected to show this fragment. As seen in the Southern blot, the transcriptionally active DNA from the 14-day globin-synthesizing cells was sensitive to DNase I digestion, indicated by the absence of the 4.6-kb band at higher nuclease concentrations. In contrast, the inactive DNA from MSB cells was resistant to digestion. These results suggest that the inactive DNA is in a more condensed form of chromatin in which the globin gene is shielded from DNase digestion. [See J. Stalder et al., 1980, *Cell* 19:973; photograph courtesy of H. Weintraub.]

and other transcription control sequences in DNA to the proteins involved in transcription, contributing to transcriptional repression (Chapter 7).

Genetic studies in yeast indicated that *histone acetyltransferases* (HATs), which acetylate specific lysine residues

in histones, are required for the full activation of transcription of a number of genes. These enzymes are now known to have other substrates that influence gene expression in addition to histones. Consequently, they are more generally known as *nuclear lysine acetyltransferases*, or KATs because K represents lysine in the single-letter code for amino acids (Figure 2-14). Conversely, early genetic studies in yeast indicated that complete repression of many yeast genes requires the action of *histone deacetylases* (HDACs) that remove acetyl groups of acetylated lysines from histone tails, as discussed further in Chapter 7.

Other Histone Modifications As shown in Figure 6-31b, histone tails in chromatin can undergo a variety of other covalent modifications at specific amino acids. Lysine ϵ -amino groups can be methylated, a process that prevents acetylation, thus maintaining their positive charge. Moreover, the N of lysine ϵ -amino groups can be methylated once, twice, or three times. Arginine side chains can also be methylated. The O in hydroxyl groups ($-\text{OH}$) of serine and threonine side chains can be reversibly phosphorylated, introducing two negative charges. Each of these post-translational modifications contributes to the binding of chromatin-associated proteins that participate in the control of chromatin folding and the ability of DNA and RNA polymerases to replicate or transcribe the associated DNA. Finally, a single 76-amino-acid ubiquitin molecule can be reversibly added to a lysine in the C-terminal tails of H2A and H2B. Recall that addition of multiple linked ubiquitin molecules to a protein can mark it for degradation by the proteasome (see Figure 3-29b). In this case, however, the addition of a single ubiquitin molecule does not affect the stability of a histone, although it does influence chromatin structure.

As mentioned previously, it is the precise combination of modified amino acids in histone tails that helps control the condensation, or compaction, of chromatin and its ability to be transcribed, replicated, and repaired. This can be observed by electron microscopy and light microscopy using dyes that bind DNA. Condensed regions of chromatin known as **heterochromatin** stain much more darkly than less condensed chromatin, known as **euchromatin** (Figure 6-33a). Heterochromatin does not fully decondense following mitosis, remaining in a compacted state during interphase and usually associating with the nuclear envelope, nucleoli, and additional distinct foci. Heterochromatin includes centromeres and telomeres of chromosomes, as well as transcriptionally inactive genes. In contrast, areas of euchromatin, which are in a less compacted state during interphase, stain lightly with DNA dyes. Most transcribed regions of DNA are found in euchromatin. Heterochromatin usually contains histone H3 modified by methylation of lysine 9 or 27, while euchromatin generally contains histone H3 extensively acetylated on lysine 9 and 14, and to a lesser extent at other H3 lysines, methylation of lysine 4, and phosphorylation of serine 10 (Figure 6-33b). Other histone tails are also specifically modified in euchromatin versus heterochromatin. For example, H4 lysine 16 is generally unacetylated in

FIGURE 6-33 Heterochromatin versus euchromatin. (a) In this electron micrograph of a bone marrow stem cell, the dark-staining areas in the nucleus (N) outside the nucleolus (n) are heterochromatin. The light-staining, whitish areas are euchromatin. (b) The modifications of histone N-terminal tails in heterochromatin and euchromatin differ, as illustrated here for histone H3. Note in particular that histone tails are generally much more extensively acetylated in euchromatin compared with heterochromatin. Heterochromatin is much more condensed (thus less accessible to proteins) and is much less transcriptionally active than is euchromatin. [Part (a) P. C. Cross and K. L. Mercer, 1993, *Cell and Tissue Ultrastructure*, W. H. Freeman and Company, p. 165. Part (b) adapted from T. Jenuwein and C. D. Allis, 2001, *Science* **293**:1074.]

heterochromatin, allowing it to interact with neighboring nucleosomes and stabilize chromatin folding into the 30-nm fiber (Figure 6-30).

Reading the Histone Code The histone code of modified amino acids in the histone tails is “read” by proteins that bind to the modified tails and in turn promote condensation or decondensation of chromatin, forming “closed” or “open” chromatin structures, as judged by their sensitivity

to DNase I digestion in isolated nuclei (see Figure 6-32). Higher eukaryotes express a number of proteins containing a so-called *chromodomain* that binds to histone tails when they are methylated at specific lysines. One example is *heterochromatin protein 1* (HP1). In addition to histones, HP1 is one of the major proteins associated with heterochromatin. The HP1 chromodomain binds the H3 N-terminal tail only when it is tri-methylated at lysine 9 (see Figure 6-33b). HP1 also contains a second domain called a *chromoshadow domain* because it is frequently found in proteins that contain a chromodomain. The chromoshadow domain binds to other chromoshadow domains. Consequently, chromatin containing H3 tri-methylated at lysine 9 (H3K9Me₃) is assembled into a condensed chromatin structure by HP1, although the structure of this chromatin is not well understood (Figure 6-34a).

In addition to binding to itself, the chromoshadow domain also binds the enzyme that methylates H3 lysine 9, an H3K9 histone methyl transferase (HMT). As a consequence, nucleosomes adjacent to a region of HP1-containing heterochromatin also become methylated at lysine 9 (Figure 6-34b). This creates a binding site for another HP1 that can bind the H3K9 histone methyl transferase, resulting in “spreading” of the heterochromatin structure along the chromosome until a *boundary element* is encountered that blocks further spreading. Boundary elements so far characterized are generally regions in chromatin where several nonhistone proteins bind to DNA, possibly blocking histone methylation on the other side of the boundary.

Significantly, the model of heterochromatin formation in Figure 6-34b provides an explanation for how heterochromatic regions of a chromosome are reestablished following DNA replication during the S phase of the cell cycle. When DNA in heterochromatin is replicated, the histone octamers that are tri-methylated at H3 lysine 9 become distributed to both daughter chromosomes along with an equal number of newly assembled histone octamers. The H3K9 histone methyl transferase associated with the H3K9 tri-methylated nucleosomes methylate lysine 9 of the newly assembled nucleosomes, regenerating the heterochromatin in both daughter chromosomes. Consequently, heterochromatin is marked with an *epigenetic code*, so called because it does not depend on the sequence of bases in DNA that maintains the repression of associated genes in replicated daughter cells.

Other protein domains associate with histone-tail modifications typical of euchromatin. For example, the *bromodomain* binds to acetylated histone tails and therefore is associated with transcriptionally active chromatin. Several proteins involved in stimulating gene transcription contain bromodomains, such as the largest subunit of TFIID (see Chapter 7). This *transcription factor* contains two closely spaced bromodomains that probably help TFIID to associate with transcriptionally active chromatin (i.e., euchromatin). This protein and other bromodomain-containing proteins also have histone acetylase activity, which helps to maintain the chromatin in a hyperacetylated state conducive to transcription. Consequently, an epigenetic code associated with

FIGURE 6-34 Model for the formation of heterochromatin by the binding of HP1 to histone H3 trimethylated at lysine 9. (a) HP1 contributes to the condensation of heterochromatin by binding to histone H3 N-terminal tails tri-methylated at lysine 9, followed by association of the histone-bound HP1. (b) Heterochromatin condensation can spread along a chromosome because HP1 binds a histone methyltransferase (HMT) that methylates lysine 9 of histone H3. This creates a binding site for HP1 on the neighboring nucleosome. The spreading process continues until a "boundary element" is encountered. [Part (a) adapted from G. Thiel et al., 2004, *Eur. J. Biochem.* **271**:2855. Part (b) adapted from A. J. Bannister et al., 2001, *Nature* **410**:120.]

euchromatin helps to maintain the transcriptional activity of genes in euchromatin through successive cell divisions. These epigenetic codes for heterochromatin and euchromatin help to maintain the patterns of gene expression established in different cell types during early embryonic development as specific differentiated cell types increase in numbers by cell division. Importantly, abnormal alterations in these epigenetic codes have been found to contribute to the pathogenic replication and behavior of cancer cells (Chapter 24).

In summary, multiple types of covalent modifications of histone tails can influence chromatin structure by altering nucleosome–nucleosome interactions and interactions with additional proteins that participate in or regulate processes such as transcription and DNA replication. The mechanisms and molecular processes governing chromatin modifications that regulate transcription are discussed in greater detail in the next chapter.

X-Chromosome Inactivation in Mammalian Females One important example of epigenetic gene control through repression by heterochromatin is the random inactivation and condensation of one of the two X chromosomes in female mammals. Each female mammal has two X chromosomes, one contributed by the egg from which it developed (X_m) and one contributed by the sperm (X_p). Early during embryonic development, random inactivation of either the X_m or the X_p chromosome occurs in each somatic cell. In the female embryo, about half the cells have an inactive X_m , and the other half have an inactive X_p . All subsequent daughter cells maintain the same inactive X chromosomes as their parent cells. As a result, the adult female is a mosaic of clones, some expressing the genes from the X_m and the rest expressing the genes from the X_p . This inactivation of one X chromosome in female mammals results in *dosage compensation*, the process that ensures that cells of females express the same level of proteins encoded on the X chromosome as the cells of males, which have only one X chromosome.

Histones associated with the inactive X chromosome have post-translational modifications characteristic of other regions of heterochromatin: hypoacetylation of lysines, di- and trimethylation of histone H3 lysine 9, tri-methylation of H3 lysine 27, and a lack of methylation at histone H3 lysine 4 (see Figure 6-33b). X-chromosome inactivation at an early stage in embryonic development is controlled by the X-inactivation center, a complex locus on the X chromosome that determines which of the two X chromosomes will be inactivated and in which cells. The X-inactivation center also contains the *Xist* gene, which encodes a remarkable, long, non-protein-coding RNA that coats only the X chromosome it was transcribed from, thereby triggering silencing of the chromosome.

Although the mechanism of X-chromosome inactivation is not fully understood, it involves several processes including the action of *Polycomb* protein complexes that are discussed further in Chapter 7. One subunit of the Polycomb complex contains a chromodomain that binds to histone H3 tails when they are tri-methylated at lysine 27. The Polycomb

complex also contains a histone methyl transferase specific for H3 lysine 27. This finding helps to explain how the X-inactivation process spreads along large regions of the X chromosome and how it is maintained through DNA replication, similar to heterochromatinization by the binding of HP1 to histone H3 tails methylated at lysine 9 (see Figure 6-34b).

X-chromosome inactivation is another example of an epigenetic process, that is, a process that affects the expression of specific genes and is inherited by daughter cells but is not the result of a change in DNA sequence. Instead, the activity of genes on the X chromosome in female mammals is controlled by chromatin structure rather than the nucleotide sequence of the underlying DNA. And the inactivated X chromosome (either X_m or X_p) is maintained as the inactive chromosome in the progeny of all future cell divisions because the histones are modified in a specific, repressing manner that is faithfully inherited through each cell division.

Nonhistone Proteins Organize Long Chromatin Loops

Although histones are the predominant proteins in chromatin, less abundant, nonhistone chromatin-associated proteins, and the DNA molecule itself, are also crucial to chromosome structure. Recent results indicate that it is not protein alone that gives a metaphase chromosome its structure. Micromechanical studies of large metaphase chromosomes from newts in the presence of proteases or nucleases indicate that DNA, not protein, is responsible for the mechanical integrity of a metaphase chromosome when it is pulled from its ends. These results are inconsistent with a continuous protein scaffold at the chromosome axis. Rather, the integrity of chromosome structure requires the complete chromatin complex of DNA, histone octamers, and nonhistone chromatin-associated proteins.

In situ hybridization experiments with several different fluorescent-labeled probes to the DNA of one chromosome in human interphase cells support a model in which chromatin is arranged in large loops. In these experiments, some probe sequences separated by millions of base pairs in linear DNA appeared reproducibly very close to one another in interphase nuclei from different cells of the same type (Figure 6-35). These closely spaced probe sites are postulated to lie close to regions of chromatin, called *scaffold-associated regions (SARs)* or *matrix-attachment regions (MARs)*, located at the bases of the DNA loops. SARs/MARs have been mapped by digesting histone-depleted chromosomes with restriction enzymes and then recovering the fragments that remain associated with the digested histone-depleted preparation. The measured distances between probes are consistent with chromatin loops ranging in size from 1 million to 4 million base pairs in mammalian interphase cells. Loops of chromatin are also directly visualized by light microscopy in the active chromatin of growing amphibian oocytes ("lampbrush chromosomes," shown in the figure at the beginning of Chapter 8). These cells are enormous compared to most cells (≈ 1 mm in diameter) because they stockpile all

EXPERIMENTAL FIGURE 6-35 Fluorescent-labeled probes hybridized to interphase chromosomes demonstrate chromatin loops and permit their measurement. In situ hybridization of interphase cells was carried out with several different probes specific for sequences separated by known distances in linear, cloned DNA. Lettered circles represent probes. Measurement of the distances between different hybridized probes, which could be distinguished by their color, showed that some sequences (e.g., A and B), separated from one another by millions of base pairs, appear located near one another within nuclei. For some sets of sequences, the measured distances in nuclei between one probe (e.g., C) and sequences successively farther away initially appear to increase (e.g., D, E, and F) and then appear to decrease (e.g., G and H). [Adapted from H. Yokota et al., 1995, *J. Cell Biol.* 130:1239.]

of the nuclear and cytoplasmic material required for division of the fertilized egg into the thousands of differentiated cells required to generate a feeding embryo that can ingest additional nutrients.

In general, SARs/MARs are found between transcription units, and genes are located primarily within the chromatin loops. As discussed below, the loops are tethered at their bases by a mechanism that does not break the duplex DNA molecule that extends the entire length of the chromosome. Evidence indicates that SARs/MARs may insulate neighboring genes. Some SARs/MARs function as *insulators*, that is, DNA sequences of tens to hundreds of base pairs that separate transcription units from each other. Proteins regulating transcription of one gene cannot influence the transcription of a neighboring gene that is separated from it by an insulator.

Ringlike Structure of SMC Protein Complexes The bases of chromatin loops (see Figure 6-35) in interphase chromosomes may be held in place by proteins called *structural maintenance of chromosome proteins*, or *SMC* proteins. These nonhistone proteins are critical for maintaining the morphological structure of condensed chromosomes during mitosis. In extracts prepared from the large nuclei of *Xenopus laevis* (African frog) eggs, chromosomes can be induced to condense as they do in intact cells as they enter the prophase period of mitosis. This condensation fails to occur when one type of SMC protein is depleted from the extract with specific

FIGURE 6-36 Model of SMC complexes bound to chromatin.

(a) Model of an SMC protein complex. (b) Model of SMC complex topologically linking two chromatin fibers represented by cylinders with the diameter of a nucleosome relative to the dimensions of the SMC complex. (c) Model for the binding of SMC complexes to the base of a loop of transcribed chromatin. [Adapted from K. Nasmyth and C. H. Haering, 2005, *Ann. Rev. Biochem.* 74:595.]

antibodies. Yeast with mutations in certain SMC proteins fail to properly associate daughter chromatids following DNA replication in the S phase. As a result, chromosomes do not properly segregate to daughter cells during mitosis. Related SMC proteins are required for proper segregation of chromosomes in bacteria and archaea, indicating that this is an ancient class of proteins vital to chromosome structure and segregation in all kingdoms of life.

Each SMC monomer contains a hinge region where the polypeptide folds back on itself, forming a very long, coiled coil region and bringing the N- and C-termini together so they can interact to form a globular head domain (Figure 6-36a).

EXPERIMENTAL FIGURE 6-37 During interphase, human chromosomes remain in nonoverlapping territories in the nucleus.

Fixed interphase human fibroblasts were hybridized in situ to fluorescently labeled probes specific for sequences along the full length of human chromosomes 7 (cyan) and 8 (purple). DNA is stained blue with DAPI. In the diploid cell, each of the two chromosome 7s and two chromosome 8s is restricted to a territory or domain within the nucleus, rather than stretching throughout the entire nucleus. (b) Similar to (a) except that chromosome paint probes specific for each chromosome were hybridized to reveal the location of nearly all of the chromosomes in a fibroblast from a human male. Some of the chromosomes are not observed in this confocal slice through the nucleus. [Part (a) courtesy of Drs. I. Solovei and T. Cremer. Part (b) from A. Bolzer et al., 2005, *PLOS Biol* 3:826.]

The hinge domain of one monomer (blue) binds to the hinge domain of a second monomer (red), forming a roughly U-shaped dimeric complex. The head domains of the monomers have ATPase activity and are linked by members of another small protein family called *kleisins*. The overall SMC complex is a ring with a diameter large enough to accommodate two 30-nm chromatin fibers (Figure 6-36b), and is capable of linking two circular DNA molecules in vitro. SMC proteins are proposed to form the base of chromatin loops by forming topologically constrained knots in 30-nm chromatin fibers, as diagrammed in Figure 6-36c. This can explain why cleavage of the DNA at a relatively small number of sites leads to rapid dissolution of condensed metaphase chromosome structure, whereas protease cleavage of proteins has only a minor effect on chromosome structure until most of the protein is digested: When the DNA is cut anywhere in a long region of chromatin containing several chromatin loops, the

broken ends can slip through the SMC protein rings, “untying” the topological knots that constrain the loops of chromatin. In contrast, most of the individual rings of SMC proteins must be broken before the topological constraints holding the base of the loops together is released.

Interphase Chromosome Territories In the small nuclei of most cells, individual interphase chromosomes, which are less condensed than metaphase chromosomes, cannot be resolved by standard microscopy or electron microscopy. Nonetheless, the chromatin of one chromosome in interphase cells is not spread throughout the nucleus. Rather, interphase chromatin is organized into *chromosome territories*. As illustrated in Figure 6-37, in situ hybridization of interphase nuclei with chromosome-specific fluorescent-labeled probes shows that the probes are visualized within restricted regions of the nucleus rather than appearing throughout the nucleus. Use of probes specific for different chromosomes shows that there is little overlap between chromosomes in interphase nuclei. However, the precise positions of chromosomes are not reproducible between cells.

Metaphase Chromosome Structure Condensation of chromosomes during prophase may involve the formation of many more loops of chromatin, so that the length of each loop is greatly reduced compared to that in interphase cells. However, the folding of chromatin in metaphase chromosomes is not well understood. Microscopic analysis of mammalian chromosomes as they condense during prophase indicates that the 30-nm fiber folds into a 100- to 130-nm fiber called a

FIGURE 6-38 Model for the folding of the 30-nm chromatin fiber in a metaphase chromosome. A single chromatid of a metaphase chromosome is depicted. [Adapted from N. Kireeva et al., 2004, *J. Cell Biol.* 166:775.]

FIGURE 6-39 Typical metaphase chromosome. As seen in this scanning electron micrograph, the chromosome has replicated and comprises two chromatids, each containing one of two identical DNA molecules. The centromere, where chromatids are attached at a constriction, is required for their separation late in mitosis. Special telomere sequences at the ends function in preventing chromosome shortening. [Andrew Syred/Photo Researchers, Inc.]

chromonema fiber. As depicted in Figure 6-38, a chromonema fiber then folds into a structure with a diameter of 200–250 nm called a *middle prophase chromatid*, which then folds into the 500- to 750-nm-diameter chromatids observed during metaphase. Ultimately, the full lengths of two associated daughter chromosomes generated by DNA replication during the previous S phase of the cell cycle condense into bar-shaped structures that in most eukaryotes are linked at the central constriction called the centromere (Figure 6-39).

Additional Nonhistone Proteins Regulate Transcription and Replication

The total mass of the histones associated with DNA in chromatin is about equal to that of the DNA. Interphase chromatin and metaphase chromosomes also contain small amounts of a complex set of other proteins. For instance, thousands

of different **transcription factors** are associated with interphase chromatin. The structure and function of these critical nonhistone proteins, which regulate transcription, are examined in Chapter 7. Other low-abundance nonhistone proteins associated with chromatin regulate DNA replication during the eukaryotic cell cycle (Chapter 20).

A few other nonhistone DNA-binding proteins are present in much larger amounts than the transcription or replication factors. Some of these exhibit high mobility during electrophoretic separation and thus have been designated *HMG (high-mobility group) proteins*. When genes encoding the most abundant HMG proteins are deleted from yeast cells, normal transcription is disturbed in most genes examined. Some HMG proteins have been found to assist in the cooperative binding of several transcription factors to specific DNA sequences that are close to each other, stabilizing multiprotein complexes that regulate transcription of a neighboring gene, as discussed in Chapter 7.

KEY CONCEPTS of Section 6.6

Structural Organization of Eukaryotic Chromosomes

- In eukaryotic cells, DNA is associated with about an equal mass of histone proteins in a highly condensed nucleoprotein complex called chromatin. The building block of chromatin is the nucleosome, consisting of a histone octamer around which is wrapped 147 bp of DNA (see Figure 6-29).
- The chromatin in transcriptionally inactive regions of DNA within cells is thought to exist in a condensed, 30-nm fiber form and higher-order structures built from it (see Figure 6-30 and 6-38).
- The chromatin in transcriptionally active regions of DNA within cells is thought to exist in an open, extended form.
- The histone H4 tails, particularly H4 lysine 16, are required for beads-on-a-string chromatin (the 10-nm chromatin fiber) to fold into a 30-nm fiber.
- Histone tails can be modified by acetylation, methylation, phosphorylation, and monoubiquitination (see Figure 6-31). These modifications influence chromatin structure by regulating the binding of histone tails to other, less abundant chromatin-associated proteins.
- The reversible acetylation and deacetylation of lysine residues in the N-termini of the core histones regulates chromatin condensation. Proteins involved in transcription, replication, and repair, and enzymes such as DNaseI can more easily access chromatin with hyperacetylated histone tails (euchromatin) than chromatin with hypoacetylated histone tails (heterochromatin).
- When metaphase chromosomes decondense during interphase, areas of heterochromatin remain much more condensed than regions of euchromatin.
- Heterochromatin protein 1 (HP1) uses a chromodomain to bind to histone H3 tri-methylated on lysine 9. The chro-

moshadow domain of HP1 also associates with itself and with the histone methyl transferase that methylates H3 lysine 9. These interactions cause condensation of the 30-nm chromatin fiber and spreading of the heterochromatic structure along the chromosome until a boundary element is encountered (see Figure 6-34).

- One X chromosome in nearly every cell of mammalian females is highly condensed heterochromatin, resulting in repression of expression of nearly all genes on the inactive chromosome. This inactivation results in dosage compensation so that genes on the X chromosome are expressed at the same level in both males and females.
- Each eukaryotic chromosome contains a single DNA molecule packaged into nucleosomes and folded into a 30-nm chromatin fiber, which is associated with a protein scaffold made up in part of structural maintenance of chromosome (SMC) proteins at sites between transcription units (see Figure 6-36c). Additional folding of the scaffold further compacts the structure into the highly condensed form of metaphase chromosomes (see Figure 6-38).

6.7 Morphology and Functional Elements of Eukaryotic Chromosomes

Having examined the detailed structural organization of chromosomes in the previous section, we now view them from a more global perspective. Early microscopic observations on the number and size of chromosomes and their staining patterns led to the discovery of many important general characteristics of chromosome structure. Researchers subsequently identified specific chromosomal regions critical to their replication and segregation to daughter cells during cell division. In this section we discuss these functional elements of chromosomes and consider how chromosomes evolved through rare rearrangements of ancestral chromosomes.

Chromosome Number, Size, and Shape at Metaphase Are Species-Specific

As noted previously, in nondividing cells, individual chromosomes are not visible, even with the aid of histologic stains for DNA (e.g., Feulgen or Giemsa stains) or electron microscopy. During mitosis and meiosis, however, the chromosomes condense and become visible in the light microscope. Therefore, almost all cytogenetic work (i.e., studies of chromosome morphology) has been done with condensed metaphase chromosomes obtained from dividing cells—either somatic cells in mitosis or dividing gametes during meiosis.

The condensation of metaphase chromosomes probably results from several orders of folding of 30-nm chromatin fibers (see Figure 6-38). At the time of mitosis, cells have already progressed through the S phase of the cell cycle and

have replicated their DNA. Consequently, the chromosomes that become visible during metaphase are *duplicated* structures. Each metaphase chromosome consists of two sister **chromatids**, which are linked at a constricted region, the centromere (see Figure 6-39). The number, sizes, and shapes of the metaphase chromosomes constitute the **karyotype**, which is distinctive for each species. In most organisms, all somatic cells have the same karyotype. However, species that appear quite similar can have very different karyotypes, indicating that similar genetic potential can be organized on chromosomes in very different ways. For example, two species of small deer—the Indian muntjac and Reeves muntjac—contain about the same total amount of genomic DNA. In one species, this DNA is organized into 22 pairs of homologous **autosomes** and two physically separate sex chromosomes. In contrast, the other species contains the smallest number of chromosomes of any mammal, only three pairs of autosomes; one sex chromosome is physically separate, but the other is joined to the end of one autosome.

During Metaphase, Chromosomes Can Be Distinguished by Banding Patterns and Chromosome Painting

Certain dyes selectively stain some regions of metaphase chromosomes more intensely than other regions, producing characteristic banding patterns that are specific for individual chromosomes. The regularity of chromosomal bands serves as useful visible landmarks along the length of each chromosome and can help to distinguish chromosomes of similar size and shape.

Today, the method of *chromosome painting* greatly simplifies differentiating chromosomes of similar size and shape. This technique, a variation of **fluorescence in situ hybridization (FISH)**, makes use of probes specific for sites scattered along the length of each chromosome. The probes are labeled with several different fluorescent dyes with distinct excitation and emission wavelengths. Probes specific for each chromosome are labeled with a predetermined fraction of each of the dyes. After the probes are hybridized to chromosomes and the excess removed, the sample is observed with a fluorescence microscope in which a detector determines the fraction of each dye present at each fluorescing position in the microscopic field. This information is conveyed to a computer, and a special program assigns a false-color image to each type of chromosome (Figure 6-40, *left*). Computer graphics allows the two homologs of each chromosome to be placed next to each other and named according to their decreasing size. Such a display clearly displays the cell's karyotype. Figure 6-40 shows a normal human male karyotype. Chromosomal painting is a powerful method for detecting an abnormal number of chromosomes, such as chromosome 21 trisomy in patients with Down syndrome, or chromosomal translocations that occur in rare individuals and in cancer cells (Figure 6-41). The use of probes with different ratios of fluorescent dyes that hybridize to distinct positions along each normal human chromosome allows finer structure analysis of the chromosomes that can more readily reveal deletions or duplications of chromosomal regions. The figure at the beginning of the chapter illustrates the use of such *multicolor FISH* in analysis of the karyotype of a normal human female.

EXPERIMENTAL FIGURE 6-40 Human chromosomes are readily identified by chromosome painting. (a) Fluorescence in situ hybridization (FISH) of human chromosomes from a male cell in mitosis

using chromosome paint probes. (b) Alignment of these painted chromosomes by computer graphics to reveal the normal human male karyotype. [Courtesy of M. R. Speicher.]

EXPERIMENTAL FIGURE 6-41 Chromosomal translocations can be analyzed using chromosome paint probes for FISH.

Characteristic chromosomal translocations are associated with certain genetic disorders and specific types of cancers. For example, in nearly all patients with chronic myelogenous leukemia, the leukemic cells contain the Philadelphia chromosome, a shortened chromosome 22 [der(22)], and an abnormally long chromosome 9 [der(9)] ("der" stands for derivative). These result from a translocation between normal chromosomes 9 and 22. This translocation can be detected by classical banding analysis diagrammed in (a) and FISH with chromosome paint probes (b). [Part (a) from J. Kuby, 1997, *Immunology*, 3d ed., W. H. Freeman and Company, p. 578. Part (b) courtesy of J. Rowley and R. Espinosa.]

Chromosome Painting and DNA Sequencing Reveal the Evolution of Chromosomes

Analysis of chromosomes from different species has provided considerable insight about how chromosomes evolved. For example, hybridization of chromosome paint probes for chromosome 16 of the tree shrew (*Tupaia belangeri*) to tree shrew metaphase chromosomes revealed the two copies of chromosome 16, as expected (Figure 6-42a). However, when the

same chromosome paint probes were hybridized to human metaphase chromosomes, most of the probes hybridized to the long arm of chromosome 10 (Figure 6-42b). Further, when multiple probes from the long arm of human chromosome 10 with different fluorescent dye labels were hybridized to human chromosome 10 and tree shrew metaphase chromosomes, tree shrew sequences homologous to each of these probes were found along tree shrew chromosome 16 in the same order that they occur on human chromosome 10.

These results indicate that during the evolution of humans and tree shrews from a common ancestor that lived ≈ 85 million years ago, a long, continuous DNA sequence on one of the ancestral chromosomes became chromosome 16 in tree shrews, but evolved into the long arm of chromosome 10 in humans. The phenomenon of genes occurring in the same order on a chromosome in two different species is referred to as conserved **synteny** (derived from Latin for "on the same ribbon"). The presence of two or more genes in a common chromosomal region in two or more species indicates a conserved syntenic segment.

The relationships between the chromosomes of many primates have been determined by cross-species hybridizations of chromosome paint probes as shown for human and tree shrew in Figure 6-42a, b. From these relationships and higher-resolution analyses of regions of synteny by DNA sequencing and other methods, it has been possible to propose the karyotype of the common ancestor of all primates based on the minimum number of chromosomal rearrangements necessary to generate the regions of synteny in chromosomes of contemporary primates.

Human chromosomes are thought to have derived from a common primate ancestor with 23 autosomes plus the X and Y sex chromosomes by several different mechanisms (Figure 6-42c). Some human chromosomes were derived without large-scale rearrangements of chromosome structure. Others are thought to have evolved by breakage of an ancestral chromosome into two chromosomes or, conversely, by fusion of two ancestral chromosomes. Still other human chromosomes appear to have been generated by exchanges of parts of the arms of distinct chromosomes, that is, by reciprocal translocation involving two ancestral chromosomes. Analysis of regions of conserved synteny between the chromosomes of many mammals indicates that chromosomal rearrangements such as breakage, fusion, and translocations occurred rarely in mammalian evolution, about once every five million years. When such chromosomal rearrangements did occur, they very likely contributed to the evolution of new species that could not interbreed with the species from which they evolved.

Chromosomal rearrangements similar to those inferred for the primate lineage have been inferred for other groups of related organisms, including invertebrate, plant, and fungi lineages. The excellent agreement between predictions of evolutionary relationships based on analysis of syntenic regions of chromosomes from organisms with related anatomical structure (i.e., among mammals, among insects with similar body organization, among similar plants, etc.) and the evolutionary relationships based on the fossil record and on the extent of

divergence of DNA sequences for homologous genes is a strong argument for the validity of evolution as the process that generated the diversity of contemporary organisms.

Interphase Polytene Chromosomes Arise by DNA Amplification

The larval salivary glands of *Drosophila* species and other dipteran insects contain enlarged interphase chromosomes that are visible in the light microscope. When fixed and stained with a dye that stains DNA, these polytene chromo-

FIGURE 6-42 Evolution of primate chromosomes. (a) Chromosome paint probes for chromosome 16 of the tree shrew (*T. belangeri*, distantly related to humans) were hybridized (yellow) to tree shrew metaphase chromosomes (red). (b) The same tree shrew chromosome 16 paint probes were hybridized to human metaphase chromosomes. (c) Proposed evolution of human chromosomes (bottom) from the chromosomes of the common ancestor of all primates (top). The proposed common primate ancestor chromosomes are numbered according to their sizes, with each chromosome represented by a different color. The human chromosomes are also numbered according to their relative sizes with colors taken from the colors of the proposed common primate ancestor chromosomes from which they were derived. Small numbers to the left of the colored regions of the human chromosomes indicate the number of the ancestral chromosome from which the region was derived. Human chromosomes were derived from the proposed chromosomes of the common primate ancestor without significant rearrangements (e.g., human chromosome 1), by fusion (e.g., human chromosome 2 by fusion of ancestral chromosomes 9 and 11), breakage (e.g., human chromosomes 14 and 15 by breakage of ancestral chromosome 5), or chromosomal translocations (e.g., a reciprocal translocation between ancestral chromosomes 14 and 21 generated human chromosomes 12 and 22). [Parts (a) and (b) Muller et al. 1999. *Cromosoma* **108**:393. Part (c) derived from L. Froenicke, 2005, *Cytogenet. Genome Res.* **108**:122.]

somes are characterized by a large number of reproducible, well-demarcated bands that have been assigned standardized numbers (Figure 6-43a). The densely staining bands represent regions where the chromatin is more condensed, and the light, interband regions, where chromatin is less condensed.

EXPERIMENTAL FIGURE 6-43 Banding on *Drosophila* polytene salivary gland chromosomes. (a) In this light micrograph of *Drosophila melanogaster* larval salivary gland chromosomes, four chromosomes can be observed (X, 2, 3, and 4), with a total of approximately 5000 distinguishable bands. The banding pattern results from reproducible packing of DNA and protein within each amplified site along the chromosome. Dark bands are regions of more highly compacted chromatin. The centromeres of all four chromosomes often appear fused at the chromocenter. The tips of chromosomes 2 and 3 are labeled (L = left arm; R = right arm), as is the tip of the X chromosome. (b) The pattern of amplification of one chromosome during five replications. Double-stranded DNA is represented by a single line. Telomere and centromere DNA are not amplified. In salivary gland polytene chromosomes, each parental chromosome undergoes ≈ 10 replications ($2^{10} = 1024$ strands). [Part (a) courtesy of J. Gall. Part (b) adapted from C. D. Laird et al., 1973, *Cold Spring Harbor Symp. Quant. Biol.* **38**:311.]

Although the molecular mechanisms that control the formation of bands in polytene chromosomes are not yet understood, the highly reproducible banding pattern seen in *Drosophila* salivary gland chromosomes provides an extremely powerful method for locating specific DNA sequences along the lengths of the chromosomes in this species. Chromosomal translocations and inversions are readily detectable in polytene chromosomes, and specific chromosomal proteins can be localized on interphase polytene chromosomes by immunostaining with specific antibodies raised against

them (see Figure 7-13). Insect polytene chromosomes offer one of the only experimental systems in all of nature where such immuno-localization studies on decondensed interphase chromosomes are possible.

A generalized amplification of DNA gives rise to the polytene chromosomes found in the salivary glands of *Drosophila*. This process, termed *polytenization*, occurs when the DNA repeatedly replicates everywhere except at the telomeres and centromere, but the daughter chromosomes do not separate. The result is an enlarged chromosome composed of many parallel copies of itself, 1024 resulting from ten such replications in *Drosophila melanogaster* salivary glands (Figure 6-43b). The amplification of chromosomal DNA greatly increases gene copy number, presumably to supply sufficient mRNA for protein synthesis in the massive salivary gland cells. The bands in *Drosophila* polytene chromosomes represent $\approx 50,000$ – $100,000$ base pairs, and the banding pattern reveals that the condensation of DNA varies greatly along these relatively short regions of an interphase chromosome.

Three Functional Elements Are Required for Replication and Stable Inheritance of Chromosomes

Although chromosomes differ in length and number among species, cytogenetic studies have shown that they all behave similarly at the time of cell division. Moreover, any eukaryotic chromosome must contain three functional elements in order to replicate and segregate correctly: (1) **replication origins** at which DNA polymerases and other proteins initiate synthesis of DNA (see Figures 4-31 and 4-33); (2) the **centromere**, the constricted region required for proper segregation of daughter chromosomes; and (3) the two ends, or **telomeres**. The yeast transformation studies depicted in Figure 6-44 demonstrated the functions of these three chromosomal elements and established their importance for chromosome function.

As discussed in Chapter 4, replication of DNA begins from sites that are scattered throughout eukaryotic chromosomes. The yeast genome contains many ≈ 100 -bp sequences, called *autonomously replicating sequences* (ARSs), that act as replication origins. The observation that insertion of an ARS into a circular plasmid allows the plasmid to replicate in yeast cells provided the first functional identification of origin sequences in eukaryotic DNA (see Figure 6-44a).

Even though circular ARS-containing plasmids can replicate in yeast cells, only about 5–20 percent of progeny cells contain the plasmid because mitotic segregation of the plasmids is faulty. However, plasmids that also carry a CEN sequence, derived from the centromeres of yeast chromosomes, segregate equally or nearly so to both mother and daughter cells during mitosis (see Figure 6-44b).

If circular plasmids containing an ARS and CEN sequence are cut once with a restriction enzyme, the resulting linear plasmids do not produce *LEU*⁺ colonies unless they contain special telomeric (TEL) sequences ligated to their ends (see Figure 6-44c). The first successful experiments involving

EXPERIMENTAL FIGURE 6-44 Yeast transfection experiments identify the functional chromosomal elements necessary for normal chromosome replication and segregation. In these experiments, plasmids containing the *LEU* gene from normal yeast cells are constructed and introduced into *leu⁻* cells by transfection. If the plasmid is maintained in the *leu⁻* cells, they are transformed to *LEU⁺* by the *LEU* gene on the plasmid and can form colonies on medium lacking leucine. (a) Sequences that allow autonomous replication (ARS) of a plasmid were identified because their insertion into a plasmid vector containing a cloned *LEU* gene resulted in a high frequency of transformation to *LEU⁺*. However, even plasmids with ARS exhibit poor segregation during mitosis, and therefore do not appear in each of the daughter cells. (b) When randomly broken pieces of genomic yeast DNA are inserted into plasmids containing ARS and *LEU*, some of the subsequently transfected cells produce large colonies, indicating that a high rate of mitotic segregation among their plasmids is facilitating the continuous growth of daughter cells. The DNA recovered from plasmids in these large colonies contains yeast centromere (CEN) sequences. (c) When *leu⁻* yeast cells are transfected with linearized plasmids containing *LEU*, ARS, and CEN, no colonies grow. Addition of telomere (TEL) sequences to the ends of the linear DNA gives the linearized plasmids the ability to replicate as new chromosomes that behave very much like a normal chromosome in both mitosis and meiosis. [See A. W. Murray and J. W. Szostak, 1983, *Nature* **305**:89, and L. Clarke and J. Carbon, 1985, *Ann. Rev. Genet.* **19**:29.]

transfection of yeast cells with linear plasmids were achieved by using the ends of a DNA molecule that was known to replicate as a linear molecule in the ciliated protozoan *Tetrahymena*. During part of the life cycle of *Tetrahymena*, much of the nuclear DNA is repeatedly copied in short pieces to form a so-called *macronucleus*. One of these repeated fragments was identified as a dimer of ribosomal DNA, the ends of which contained a repeated sequence $(G_4T_2)_n$. When a section of this repeated TEL sequence was ligated to the ends of linear yeast plasmids containing ARS and CEN, replication and good segregation of the linear plasmids occurred. This first cloning and characterization of telomeres garnered the Nobel Prize in Medicine and Physiology in 2009.

Centromere Sequences Vary Greatly in Length and Complexity

Once the yeast centromere regions that confer mitotic segregation were cloned, their sequences could be determined and compared, revealing three regions (I, II, and III) that are conserved between the centromeres on different yeast chromosomes (Figure 6-45a). Short, fairly well conserved nucleotide sequences are present in regions I and III. Region II does not have a specific sequence, but is A-T rich with a fairly constant length, probably so that regions I and III lie on the same side of a specialized centromere-associated histone octamer. This specialized centromere-associated histone octamer contains

FIGURE 6-45 Kinetochore-microtubule interaction in *S. cerevisiae*. (a) Sequence of the simple centromeres of *S. cerevisiae*. (b) The Ndc80 complexes associate with both the microtubule and the CBF3 complex. (c) Diagram of the centromere-associated CBF3 complex and its associated Ndc80 complexes that associate with a ring of Dam1 proteins at the end of a spindle microtubule. The Ndc80

complexes initially make lateral interactions with the side of a spindle microtubule (*top*) and then associate with the Dam1 ring, making an end-on attachment (*bottom*) to the microtubule. [Part (a) from L. Clarke and J. Carbon, 1985, *Ann. Rev. Genet.* **19**:29. Parts (b) and (c) adapted from T. U. Tanaka, 2010, *EMBO J.* **29**:4070.]

the usual histones H2A, H2B, and H4, but a variant form of histone H3. Centromeres from all eukaryotes similarly contain nucleosomes with a specialized, centromere-specific form of histone H3, called CENP-A in humans. In *S. cerevisiae* the CBF3 complex of proteins associates with this specialized nucleosome. The CBF3 complex in turn associates with multiprotein elongated Ndc80 complexes (Figure 6-45b) that initially make lateral interactions with a spindle microtubule

and subsequently interact with a Dam1 complex that forms a ring around the end of the microtubule (Figure 6-45c). This results in an end-on interaction of the centromere with the spindle microtubule. *S. cerevisiae* has by far the simplest centromere known in nature.

In the fission yeast *S. pombe*, centromeres are ≈ 40 –100 kb in length and are composed of repeated copies of sequences similar to those in *S. cerevisiae* centromeres. Multiple copies

FIGURE 6-46 Standard DNA replication leads to loss of DNA at the 5' end of each strand of a linear DNA molecule. Replication of the right end of a linear DNA is shown; the same process occurs at the left end (shown by inverting the figure). As the replication fork approaches the end of the parental DNA molecule, the leading strand can be synthesized all the way to the end of the parental template strand without the loss of deoxyribonucleotides. However, since synthesis of the lagging strand requires RNA primers, the right end of the lagging daughter DNA strand would remain as ribonucleotides which are removed and therefore cannot serve as the template for a replicative DNA polymerase. Alternative mechanisms must be utilized to prevent successive shortening of the lagging strand with each round of replication. [Adapted from the Nobel Assembly at the Karolinska Institute.]

of proteins homologous to those that interact with *S. cerevisiae* centromeres bind to these complex *S. pombe* centromeres and in turn bind the much longer *S. pombe* chromosomes to several microtubules of the mitotic spindle apparatus. In plants and animals, centromeres are megabases in length and are composed of multiple repeats of simple-sequence DNA. In humans, centromeres contain 2- to 4-megabase arrays of a 171-bp simple-sequence DNA called *alphoid* DNA that is bound by nucleosomes containing the CENP-A histone H3 variant, as well as other repeated simple-sequence DNA.

In higher eukaryotes, a complex protein structure called the **kinetochore** assembles at centromeres and associates with multiple mitotic spindle fibers during mitosis (see Figure 18-39). Homologs of many of the centromere-associated proteins found in the yeasts occur in humans and other higher eukaryotes. For those yeast proteins where clear homologs are not evident in higher cells based on amino acid sequence comparisons (such as the Dam1 complex), alternative complexes with similar properties have been proposed to function at kinetochores that are bound to multiple spindle microtubules. The function of the centromere and kinetochore proteins that bind to it during the segregation of sister chromatids in mitosis and meiosis is described in Chapters 18 and 19.

Addition of Telomeric Sequences by Telomerase Prevents Shortening of Chromosomes

Sequencing of telomeres from multiple organisms, including humans, has shown that most are repetitive oligomers with a high G content in the strand with its 3' end at the end of the chromosome. The telomere repeat sequence in humans and other vertebrates is TTAGGG. These simple sequences are repeated at the very termini of chromosomes for a total of a few hundred base pairs in yeasts and protozoans, and a few thousand base pairs in vertebrates. The 3' end of the G-rich strand extends 12–16 nucleotides beyond the 5' end of the complementary C-rich strand. This region is bound by specific proteins that protect the ends of linear chromosomes from attack by exonucleases.

The need for a specialized region at the ends of eukaryotic chromosomes is apparent when we consider that all known DNA polymerases elongate DNA chains at the 3' end, and all require an RNA or DNA primer. As the replication fork approaches the end of a linear chromosome, synthesis of the leading strand continues to the end of the DNA template strand, completing one daughter DNA double helix. However, because the lagging-strand template is copied in a discontinuous fashion, it cannot be replicated in its entirety (Figure 6-46). When the final RNA primer is removed, there is no upstream strand onto which DNA polymerase can build to fill the resulting gap. Without some special mechanism, the daughter DNA strand resulting from lagging-strand synthesis would be shortened at each cell division.

The problem of telomere shortening is solved by an enzyme that adds telomeric (TEL) repeat sequences to the ends of each chromosome. The enzyme is a protein–RNA complex called *telomere terminal transferase*, or *telomerase*. Because the sequence of the telomerase-associated RNA, as we will see, serves as the template for addition of deoxyribonucleotides to the ends of telomeres, the source of the enzyme and not the source of the telomeric DNA primer determines the sequence added. This was proven by transforming *Tetrahymena* with a mutated form of the gene encoding the telomerase-associated RNA. The resulting telomerase added a DNA sequence complementary to the mutated RNA sequence to the

FIGURE 6-47 Mechanism of action of telomerase. The single-stranded 3' terminus of a telomere is extended by telomerase, counteracting the inability of the DNA replication mechanism to synthesize the extreme terminus of linear DNA. Telomerase elongates this single-stranded end by a reiterative reverse-transcription mechanism. The action of the telomerase from the protozoan *Tetrahymena*, which adds a T₂G₄ repeat unit, is depicted; other telomerases add slightly different sequences. The telomerase contains an RNA template (red) that base-pairs to the 3' end of the lagging-strand template. The telomerase catalytic site then adds deoxyribonucleotides TTG (blue) using the RNA molecule as a template (step 1). The strands of the resulting DNA-RNA duplex are then thought to slip (translocate) relative to each other so that the TTG sequence at the 3' end of the replicating DNA base-pairs to the complementary RNA sequence in the telomerase RNA (step 2). The 3' end of the replicating DNA is again extended by telomerase (step 3). Telomerases can add multiple repeats by repetition of steps 2 and 3. DNA polymerase α -primase can prime synthesis of new Okazaki fragments on this extended template strand. The net result prevents shortening of the lagging strand at each cycle of DNA replication [From C.W. Greider and E. H. Blackburn, 1989, *Nature* 337:331.]

ends of telomeric primers. Thus telomerase is a specialized form of a reverse transcriptase that carries its own internal RNA template to direct DNA synthesis. These experiments also earned the Nobel Prize in Physiology and Medicine for the discovery and characterization of the mechanism of telomerase.

Figure 6-47 depicts how telomerase, by reverse transcription of its associated RNA, elongates the 3' end of the single-stranded DNA at the end of the G-rich strand mentioned above. Cells from knockout mice that cannot produce the telomerase-associated RNA exhibit no telomerase activity, and their telomeres shorten successively with each cell generation. Such mice can breed and reproduce normally for three generations before the long telomere repeats become substantially eroded. Then, the absence of telomere DNA results in adverse effects, including fusion of chromosome termini and chromosomal loss. By the fourth generation, the reproductive potential of these knockout mice declines, and they cannot produce offspring after the sixth generation.

 The human genes expressing the telomerase protein and the telomerase-associated RNA are active in germ cells and stem cells, but are turned off in most cells of adult tissues that replicate only a limited number of times, or will never replicate again (such cells are called *postmitotic*). However, these genes are activated in most human cancer cells, where telomerase is required for the multiple cell divisions necessary to form a tumor. This phenomenon has stimulated a search for inhibitors of human telomerase as potential therapeutic agents for treating cancer. ■

While telomerase prevents telomere shortening in most eukaryotes, some organisms use alternative strategies. *Drosophila*

species maintain telomere lengths by the regulated insertion of non-LTR retrotransposons into telomeres. This is one of the few instances in which a mobile element has a specific function in its host organism.

KEY CONCEPTS of Section 6.7

Morphology and Functional Elements of Eukaryotic Chromosomes

- During metaphase, eukaryotic chromosomes become sufficiently condensed that they can be visualized individually in the light microscope.
- The chromosomal karyotype is characteristic of each species. Closely related species can have dramatically different karyotypes, indicating that similar genetic information can be organized on chromosomes in different ways.
- Banding analysis and chromosome painting are used to identify the different human metaphase chromosomes and to detect translocations and deletions (see Figure 6-41).
- Analysis of chromosomal rearrangements and regions of conserved synteny between related species allows scientists

to make predictions about the evolution of chromosomes (see Figure 6-42c). The evolutionary relationships between organisms indicated by these studies are consistent with proposed evolutionary relationships based on the fossil record and DNA sequence analysis.

- The highly reproducible banding patterns of polytene chromosomes make it possible to visualize chromosomal deletions and rearrangements as changes in the normal pattern of bands.
- Three types of DNA sequences are required for a long linear DNA molecule to function as a chromosome: a replication origin, called ARS in yeast; a centromere (CEN) sequence; and two telomere (TEL) sequences at the ends of the DNA (see Figure 6-44).
- Telomerase, a protein–RNA complex, has a special reverse transcriptase activity that completes replication of telomeres during DNA synthesis (see Figure 6-47). In the absence of telomerase, the daughter DNA strand resulting from lagging-strand synthesis would be shortened at each cell division in most eukaryotes (see Figure 6-46).

Perspectives for the Future

The human genome sequence is a goldmine for new discoveries in molecular cell biology, in identifying new proteins that may be the basis of effective therapies of human diseases, and for understanding early human history and evolution. However, finding new genes is like finding a needle in a haystack, because only ≈ 1.5 percent of the sequence encodes proteins or functional RNA. Identification of genes in bacterial genome sequences is relatively simple because of the scarcity of introns; simply searching for long open reading frames free of stop codons identifies most genes. In contrast, the search for human genes is complicated by the structure of human genes, most of which are composed of multiple, relatively short exons separated by much longer, noncoding introns. Identification of complex transcription units by analysis of genomic DNA sequences alone is extremely challenging. Future improvements in bioinformatic methods for gene identification, and characterization of cDNA copies of mRNAs isolated from the hundreds of human cell types, will likely lead to the discovery of new proteins, to a better understanding of biological processes, and may lead to applications in medicine and agriculture.

We have seen that although most transposons do not function directly in cellular processes, they have helped to shape modern genomes by promoting gene duplications, exon shuffling, the generation of new combinations of transcription-control sequences, and other aspects of contemporary genomes. They are also teaching us about our own history and origins, because L1 and *Alu* retrotransposons have

inserted into new sites in individuals throughout our history. Large numbers of these interspersed repeats are polymorphic within populations, occurring at a particular site in some individuals and not others. Individuals sharing an insertion at a particular site descended from a common ancestor that developed from an egg or sperm in which that insertion occurred. The time elapsed from the initial insertion can be estimated by the differences in sequences of the element that arose from the accumulation of random mutations. Further analysis of retrotransposon polymorphisms will undoubtedly add immensely to our understanding both of human migrations since *Homo sapiens* first evolved, as well as the history of contemporary populations.

As described in Chapter 5, the *Drosophila* P-element DNA transposon was exploited for the facile stable transformation of genes into the *Drosophila* germ line. This has been a powerful method for molecular cell biology experimentation in this organism. An active area of current research is to use mammalian transposons and retrotransposons for the transformation of human cells for gene therapy. This promises to be an exciting area of medicine in the future treatment of genetic diseases such as sickle-cell anemia and cystic fibrosis as well as more common diseases, especially when coupled with the recently developed techniques for generating pluripotent stem cells (iPS cells) from differentiated cells of a pediatric or adult patient (Chapter 21).

Key Terms

bioinformatics 252	matrix-associated regions (MARs) 263
centromere 270	monocistronic 225
chromatid 267	nucleosome 225

Review the Concepts

1. Genes can be transcribed into mRNA for protein-coding genes or into RNA for genes such as ribosomal or transfer RNAs. Define a gene. For the following characteristics, state whether they apply to (a) continuous, (b) simple, or (c) complex transcription units.

- (i) Found in eukaryotes
- (ii) Contain introns
- (iii) Only capable of making a single protein from a given gene

2. Sequencing of the human genome has revealed much about the organization of genes. Describe the differences between solitary genes, gene families, pseudogenes, and tandemly repeated genes.

3. Much of the human genome consists of repetitious DNA. Describe the difference between microsatellite and minisatellite DNA. How is this repetitious DNA useful for identifying individuals by the technique of DNA fingerprinting?

4. Mobile DNA elements that can move or transpose to a new site directly as DNA are called DNA transposons. Describe the mechanism by which a bacterial DNA transposon, called an insertion sequence, can transpose.

5. Retrotransposons are a class of mobile elements that transpose via an RNA intermediate. Contrast the mechanism of transposition between retrotransposons that contain long terminal repeats (LTRs) and those that lack LTRs.

6. Discuss the role that transposons may have played in the evolution of modern organisms. What is exon shuffling? What role do transposons play in the process of exon shuffling?

7. Mitochondria and chloroplasts are thought to have evolved from symbiotic bacteria present in nucleated cells. What is the experimental evidence from this chapter that supports this hypothesis?

8. What are paralogous and orthologous genes? What are some of the explanations for the finding that humans are a much more complex organism than the roundworm *C. elegans*, yet have only fewer than one and a half as many genes (25,000 versus 18,000)?

9. The DNA in a cell associates with proteins to form chromatin. What is a nucleosome? What role do histones play in nucleosomes? How are nucleosomes arranged in condensed 30-nm fibers?

10. How do chromatin modifications regulate transcription? What modifications are observed in regions of the genome that are actively being transcribed? What about for regions that are not actively transcribed?

11. Describe the general organization of a eukaryotic chromosome. What structural role do scaffold-associated regions (SARs) or matrix attachment regions (MARs) play? Why does it make sense that protein-coding genes are not located in these regions?

12. What is FISH? Briefly describe how it works. How is FISH used to characterize chromosomal translocations associated with certain genetic disorders and specific types of cancers?

13. What is chromosome painting, and how is this technique useful? How can chromosome paint probes be used to analyze the evolution of mammalian chromosomes?

14. Certain organisms contain cells that possess polytene chromosomes. What are polytene chromosomes, where are they found, and what function do they serve?

15. Replication and segregation of eukaryotic chromosomes require three functional elements: replication origins, a centromere, and telomeres. How would a chromosome be affected if it lacked (a) replication origins or (b) a centromere?

16. Describe the problem that occurs during DNA replication at the ends of chromosomes. How are telomeres related to this problem?

Analyze the Data

1. To determine whether gene transfer from an organelle genome to the nucleus can be observed in the laboratory, a chloroplast transformation vector was constructed that contained two selectable antibiotic-resistance markers, each with its own promoter: the spectinomycin-resistance gene and the kanamycin-resistance gene (see S. Stegemann et al., 2003, *Proc. Nat'l Acad. Sci. USA* 100:8828–8833). The spectinomycin-resistance gene was controlled by a chloroplast promoter, yielding a chloroplast-specific selectable marker. Plants grown on spectinomycin are white unless they express the spectinomycin-resistance gene in the chloroplast. The kanamycin-resistance gene, inserted into the plasmid adjacent to the spectinomycin-resistance gene, was under the control of a strong nuclear promoter. Transgenic, spectinomycin-resistant tobacco plants were selected following transformation with this plasmid by identifying green plants grown on medium with spectinomycin. These plants contain the two antibiotic-resistance genes inserted into the chloroplast genome by a recombination event; however, kanamycin resistance is not expressed because it is under the control of a nuclear promoter. These spectinomycin-resistant plants were grown for multiple generations and used in the following studies.

a. Leaves from the spectinomycin-resistant transgenic plants were placed in a plant-regeneration medium containing kanamycin. Some of the leaf cells were resistant to kanamycin, and grew into kanamycin-resistant plants. Pollen (paternal) from kanamycin-resistant plants was used to pollinate wild-type (nontransgenic) plants. In tobacco, no chloroplasts are inherited from pollen. The resulting seeds were germinated on media with and without kanamycin. Half of the resulting seedlings were kanamycin resistant. When these kanamycin-resistant plants were allowed to self-pollinate, the offspring exhibited a 3:1 ratio of kanamycin-resistant to sensitive phenotypes. What can be deduced from these data about the location of the kanamycin-resistance gene?

b. To determine whether transfer of the kanamycin-resistance gene to the nucleus was mediated via DNA or an RNA intermediate, DNA was extracted from 10 seedling plants germinated from seeds produced by a wild-type plant

pollinated with a kanamycin-resistant plant. The 10 seedling plants, numbered 1–10 in the corresponding gel lanes in the figure below, consist of 5 kanamycin-resistant (+) and 5 kanamycin-sensitive (–) plants. Each DNA sample was subjected to PCR analysis using primers to amplify the kanamycin-resistance gene (gel at left) or the spectinomycin-resistance gene (gel at right). The lane marked M shows molecular weight markers. What does the correspondence between the presence or absence of PCR products generated in the same plant with both sets of primers suggest about the mode of transfer of the kanamycin gene to the nucleus?

c. When the original transgenic plants, which were selected on spectinomycin but not on kanamycin, were used to pollinate wild-type plants, none of the offspring were kanamycin resistant. What can be deduced from these observations?

2. Satellite DNA is a known component of our genome and can be found in both coding and noncoding DNA. When it is found in coding DNA, the number of repeats can result in altered proteins. But the effect of these repeats in noncoding DNA is not as well understood. To determine whether repeats in the promoter region can alter gene expression and chromatin compaction, Vences et al. (Vences et al., 2009, *Science* 324:1213–1216) searched the *Sacharomyces cerevisiae* genome for the presence of repetitive DNA in promoters and examined how altering the number of repeats affected gene expression and DNA packaging.

a. The group first searched for satellite DNA in the genome of various *S. cerevisiae* strains and found that 25 percent of promoters contained at least one repeat region. In addition, a single promoter in different strains often contained distinct numbers of repeats in each region of satellite DNA. What is the proposed mechanism by which the number of repeats in a given region of satellite DNA can increase?

b. To determine whether there is a correlation between the number of repeats and gene expression, transcription at the SDT1 gene was analyzed. The SDT1 promoter contains satellite DNA, and the number of repeats in this region was modified, ranging between 0 repeats to 60 repeats. It was discovered that SDT1 expression, analyzed by quantitative reverse transcriptase PCR (Q RT-PCR, see Chapter 5), increased when the repeat number increased from 0 to 13 repeats. SDT1

expression then progressively decreased as the repeat number increased from 13 to 60. What conclusion can be made based on these experimental results? Explain how Q RT-PCR can be used to analyze SDT1 gene expression.

c. The conclusion from part (b) then led the group to determine whether a cell can adapt to its surroundings by altering the number of repeats in promoter satellite DNA. The promoter from the SDT1 gene (containing 48 repeats) was attached to the URA3 open reading frame, a gene responsible for synthesis of the nucleotide uracil. Cells with this hybrid protein were then placed on media lacking uracil or media containing uracil. After growth on each media, the number of repeats in the promoter driving URA3 expression was analyzed. Those that were grown on the media lacking uracil showed a decrease in the number of repeats in the promoter, while those grown with uracil still had on average 48 repeats. What conclusion can be made from these results? Based on the data in part (b), how many repeats were likely found in the URA3 promoters for cells grown without uracil?

d. The location of the repeat DNA in the promoters was compared to the location of nucleosomes, and it was found that the nucleosome density in a promoter was inversely correlated with the number of repeats at that location of DNA. From this, what would you conclude about repetitive DNA and chromatin packaging? What effect would decreasing the repeat regions have on histone core binding at that DNA?

In previous chapters we have seen that the properties and functions of each cell type are determined by the proteins it contains. In this and the next chapter, we consider how the kinds and amounts of the various proteins produced by a particular cell type in a multicellular organism are regulated. This regulation of **gene expression** is the fundamental process that controls the development of a multicellular organism such as ourselves from a single fertilized egg cell into the thousands of cell types from which we are made. When gene expression goes awry, cellular properties are altered, a process that all too often leads to the development of cancer. As discussed further in Chapter 25, genes encoding proteins that restrain cell growth are abnormally repressed in cancer cells, whereas genes encoding proteins that promote cell growth and replication are inappropriately activated in cancer cells. Abnormalities in gene expression also result in developmental defects such as cleft palate, tetralogy of Fallot (a serious developmental defect of the heart that can be treated surgically), and many others. Regulation of gene expression also plays a vital role in bacteria and other single-celled microorganisms, where it allows cells to adjust their enzymatic machinery and structural components in response to their changing nutritional and physical environment. Consequently, to understand how microorganisms respond to their environment and how multicellular organisms normally

Transcriptional Control of Gene Expression

develop, as well as how pathological abnormalities of gene expression occur, it is essential to understand the molecular interactions that control protein production.

The basic steps in gene expression, i.e., the entire process whereby the information encoded in a particular gene is decoded into a particular protein, are reviewed in Chapter 4. Synthesis of mRNA requires that an **RNA polymerase** initiate transcription (**initiation**), polymerize ribonucleoside triphosphates complementary to the DNA coding strand (**elongation**), and then terminate transcription (**termination**) (see Figure 4-11). In bacteria, ribosomes and translation-initiation factors have immediate access to newly formed RNA transcripts, which function as mRNA without further modification. In eukaryotes, however, the initial RNA transcript is subjected to processing that yields a functional mRNA (see Figure 4-15). The mRNA then is transported from its site of synthesis in the nucleus to the cytoplasm, where it is translated into protein with the aid of ribosomes, tRNAs, and translation factors (see Figures 4-24, 4-25, and 4-27).

Regulation may occur at several of the various steps in gene expression outlined above: transcription initiation, elongation, RNA processing, mRNA export from the nucleus, and translation into protein. This results in *differential* production of proteins in different cell types or developmental stages or in response to external conditions. Although examples of

regulation at each step in gene expression have been found, control of transcription initiation and elongation—the first two steps—are the most important mechanisms for determining whether most genes are expressed and how much of the encoded mRNAs and, consequently, proteins are produced. The molecular mechanisms that regulate transcription initiation and elongation are critical to numerous biological phenomena, including the development of a multicellular organism from a single fertilized egg cell as mentioned above, the immune responses that protect us from pathogenic microorganisms, and

neurological processes such as learning and memory. When these regulatory mechanisms controlling transcription function improperly, pathological processes may occur. For example, reduced activity of the *Pax6* gene causes *aniridia*, failure to develop an iris (Figure 7-1a). *Pax6* is a **transcription factor** that normally regulates transcription of genes involved in eye development. In other organisms, mutations in transcription factors cause an extra pair of wings to develop in *Drosophila* (Figure 7-1b), alter the structures of flowers in plants (Figure 7-1c), and are responsible for multiple other developmental abnormalities.

FIGURE 7-1 Phenotypes of mutations in genes encoding transcription factors. (a) A mutation that inactivates one copy of the *Pax6* gene on either the maternal or paternal chromosome 9 results in failure to develop an iris, or *aniridia*. (b) Homozygous mutations that prevent expression of the *Ubx* gene in the third thoracic segment of *Drosophila* result in transformation of the third segment, which normally has a balancing organ called a haltere, into a second copy of the thoracic segment that develops wings. (c) Mutations in *Arabidopsis*

thaliana that inactivate both copies of three floral organ-identity genes transform the normal parts of the flower into leaflike structures. In each case, these mutations affect master regulatory transcription factors that regulate multiple genes, including many genes encoding other transcription factors. Meyerowitz, 1994, *Cell* **78**:203.]

Transcription is a complex process involving many layers of regulation. In this chapter, we focus on the molecular events that determine when transcription of a gene occurs. First, we consider the mechanisms of gene expression in bacteria, where DNA is not bound by histones and packaged into nucleosomes. **Repressor** and **activator** proteins recognize and bind to specific regions of DNA to control the transcription of a nearby gene. The remainder of the chapter focuses on eukaryotic transcription regulation and how the basic tenets of bacterial regulation are applied in more complex ways in higher organisms. These mechanisms also make use of the association of DNA with histone octamers, forming chromatin structures with varying degrees of condensation and post-translational modifications such as acetylation and methylation to regulate transcription. Figure 7-2 provides an overview of transcription regulation in metazoans (multicellular animals) and the processes outlined in this chapter. We discuss how specific DNA sequences function as **transcription-control** regions by serving

as the binding sites for transcription factors (repressors and activators) and how the RNA polymerases responsible for transcription bind to **promoter** sequences to initiate the synthesis of an RNA molecule complementary to template DNA. Next, we consider how activators and repressors influence transcription through interactions with large, multiprotein complexes. Some of these multiprotein complexes modify chromatin condensation, altering access of chromosomal DNA to transcription factors and RNA polymerases. Other complexes influence the rate at which RNA polymerase binds to DNA at the site of transcription initiation, as well as the frequency of initiation. Very recent research has revealed that, in multicellular animals, for many genes, the RNA polymerase pauses after transcribing a short RNA and transcription regulation involves a release of the paused polymerase, allowing it to transcribe through the rest of the gene. We discuss how transcription of specific genes can be specified by particular combinations of the ≈ 2000 transcription factors encoded in

FIGURE 7-2 Overview of eukaryotic transcription control. Inactive genes are assembled into regions of condensed chromatin that inhibit RNA polymerases and their associated general transcription factors (GTFs) from interacting with promoters. Activator proteins bind to specific DNA sequence-control elements in chromatin and interact with multiprotein chromatin co-activator complexes to decondense chromatin and the multisubunit mediator to assemble RNA polymerase and general transcription factors on promoters. Alternatively, repressor proteins bind to other control elements to inhibit initiation by RNA polymerase and interact with multiprotein co-repressor complexes to condense chromatin. RNA polymerase initiates transcription but pauses after transcribing 20–50 nucleotides due to the action of elongation inhibitors. Activators promote the association of elongation factors that release the elongation inhibitors and allow productive elongation through the gene. DSIF is the DRB sensitivity-inducing factor, NELF is the negative elongation factor, and P-TEFb is a protein kinase comprised of CDK9 and cyclin T. [Adapted from S. Malik and R. G. Roeder, 2010, *Nat. Rev. Genet.* 11:761.]

the human genome, giving rise to cell-type-specific gene expression. We will consider the various ways in which the activities of transcription factors themselves are controlled to ensure that genes are expressed only at the right time and in the right place. We will also discuss recent studies revealing that RNA-protein complexes in the nucleus can regulate transcription. New methods for sequencing DNA coupled with reverse transcription of RNA into DNA *in vitro* have revealed that much of the genome of eukaryotes is transcribed into low-abundance RNAs that do not encode protein, raising the possibility that transcription control by such noncoding RNAs may be a much more general process than is currently understood. RNA processing and various post-transcriptional mechanisms for controlling eukaryotic gene expression are covered in the next chapter. Subsequent chapters, particularly Chapters 15, 16, and 21, provide examples of how transcription is regulated by interactions between cells and how the resulting **gene control** contributes to the development and function of specific types of cells in multicellular organisms.

7.1 Control of Gene Expression in Bacteria

Since the structure and function of a cell are determined by the proteins it contains, the control of gene expression is a fundamental aspect of molecular cell biology. Most commonly, the “decision” to transcribe the gene encoding a particular protein is the major mechanism for controlling production of the encoded protein in a cell. By controlling transcription, a cell can regulate which proteins it produces and how rapidly. When transcription of a gene is *repressed*, the corresponding mRNA and encoded protein or proteins are synthesized at low rates. Conversely, when transcription of a gene is *activated*, both the mRNA and encoded protein or proteins are produced at much higher rates.

In most bacteria and other single-celled organisms, gene expression is highly regulated in order to adjust the cell's enzymatic machinery and structural components to changes in the nutritional and physical environment. Thus, at any given time, a bacterial cell normally synthesizes only those proteins of its entire proteome that are required for survival under particular conditions. Here we describe the basic features of transcription control in bacteria, using the *lac* operon and the glutamine synthetase gene in *E. coli* as our primary examples. Many of the same processes, as well as others, are involved in eukaryotic transcription control, which is the subject of the remainder of this chapter.

Transcription Initiation by Bacterial RNA Polymerase Requires Association with a Sigma Factor

In *E. coli*, about half the genes are clustered into **operons**, each of which encodes enzymes involved in a particular metabolic pathway or proteins that interact to form one multisubunit protein. For instance, the *trp* operon discussed in Chapter 4

encodes five polypeptides needed in the biosynthesis of tryptophan (see Figure 4-13). Similarly, the *lac* operon encodes three proteins required for the metabolism of lactose, a sugar present in milk. Since a bacterial operon is transcribed from one start site into a single mRNA, all the genes within an operon are **coordinately regulated**; that is, they are all activated or repressed to the same extent.

Transcription of operons, as well as of isolated genes, is controlled by interplay between RNA polymerase and specific repressor and activator proteins. In order to initiate transcription, however, *E. coli* RNA polymerase must be associated with one of a small number of σ (*sigma*) factors. The most common one in eubacterial cells is σ^{70} . σ^{70} binds to RNA polymerase and to promoter DNA sequences, bringing the RNA polymerase enzyme to a promoter. σ^{70} recognizes and binds to both a six-base-pair sequence centered at ≈ -10 and a seven-base-pair sequence centered at ≈ -35 from the +1 transcription start. Consequently, the -10 plus the -35 sequences constitute a promoter for *E. coli* RNA polymerase associated with σ^{70} (see Figure 4-10b). Although the promoter sequences contacted by σ^{70} are located at -35 and -10 , *E. coli* RNA polymerase binds to the promoter region DNA from ≈ -50 to $\approx +20$ through interactions with DNA that do not depend on the sequence. σ^{70} also assists the RNA polymerase in separating the DNA strands at the transcription start site and inserting the coding strand into the active site of the polymerase so that transcription starts at +1 (see Figure 4-11, step 2). The optimal σ^{70} -RNA polymerase promoter sequence, determined as the “consensus sequence” of multiple strong promoters, is

The consensus sequence has the most commonly occurring base at each of the positions in the -35 and -10 regions. The size of the font indicates the importance of the base at that position, determined by the influence of mutations of these bases. The sequence shows the strand of DNA that has the same $5' \rightarrow 3'$ orientation as the transcribed RNA (i.e., the nontemplate strand). However, the σ^{70} -RNA polymerase initially binds to double-stranded DNA. After the polymerase transcribes a few tens of base pairs, σ^{70} is released. Thus σ^{70} acts as an *initiation factor* that is required for transcription initiation but not for RNA strand elongation once initiation has taken place.

Initiation of *lac* Operon Transcription Can Be Repressed and Activated

When *E. coli* is in an environment that lacks lactose, synthesis of *lac* mRNA is repressed so that cellular energy is not wasted synthesizing enzymes the cells cannot use. In an environment containing both lactose and glucose, *E. coli* cells preferentially metabolize glucose, the central molecule of carbohydrate metabolism. Lactose is metabolized at a high rate only when lactose is present and glucose is largely depleted from the medium. This metabolic adjustment is achieved by repressing transcription of the *lac* operon until

lactose is present and allowing synthesis of only low levels of *lac* mRNA until the cytosolic concentration of glucose falls to low levels. Transcription of the *lac* operon under different conditions is controlled by *lac* repressor and catabolite activator protein (CAP) (also called CRP, for catabolite receptor protein), each of which binds to a specific DNA sequence in the *lac* transcription-control region called the operator and the CAP site, respectively (Figure 7-3, top).

For transcription of the *lac* operon to begin, the σ^{70} subunit of the RNA polymerase must bind to the *lac* promoter at the -35 and -10 promoter sequences. When no lactose is present, the *lac* repressor binds to the *lac* operator, which overlaps the transcription start site. Therefore, *lac* repressor bound to the operator site blocks σ^{70} binding and hence transcription initiation by RNA polymerase (Figure 7-3a). When lactose is present, it binds to specific binding sites in each subunit of the tetrameric *lac* repressor, causing a conformational change in the protein that makes it dissociate from the *lac*

FIGURE 7-3 Regulation of transcription from the *lac* operon of *E. coli*. (Top) The transcription-control region, composed of ≈ 100 base pairs, includes three protein-binding regions: the CAP site, which binds catabolite activator protein; the *lac* promoter, which binds the σ^{70} -RNA polymerase complex; and the *lac* operator, which binds *lac* repressor. The *lacZ* gene encoding the enzyme β -galactosidase, the first of three genes in the operon, is shown to the right. (a) In the absence of lactose, very little *lac* mRNA is produced because the *lac* repressor binds to the operator, inhibiting transcription initiation by σ^{70} -RNA polymerase. (b) In the presence of glucose and lactose, *lac* repressor binds lactose and dissociates from the operator, allowing σ^{70} -RNA polymerase to initiate transcription at a low rate. (c) Maximal transcription of the *lac* operon occurs in the presence of lactose and absence of glucose. In this situation, cAMP increases in response to the low glucose concentration and forms the CAP-cAMP complex, which binds to the CAP site, where it interacts with RNA polymerase to stimulate the rate of transcription initiation. (d) The tetrameric *lac* repressor binds to the primary *lac* operator (*O1*) and one of two secondary operators (*O2* or *O3*) simultaneously. The two structures are in equilibrium. [Part (d) adapted from B. Muller-Hill, 1998, *Curr. Opin. Microbiol.* 1:145.]

operator. As a result, the polymerase can bind to the promoter and initiate transcription of the *lac* operon. However, when glucose also is present, the rate of transcription initiation (i.e., the number of times per minute different RNA polymerase molecules initiate transcription) is very low, resulting in synthesis of only low levels of *lac* mRNA and the proteins encoded in the *lac* operon (Figure 7-3b). The frequency of transcription initiation is low because the -35 and -10 sequences in the *lac* promoter differ from the ideal σ^{70} -binding sequences shown previously.

Once glucose is depleted from the medium and the intracellular glucose concentration falls, *E. coli* cells respond by synthesizing cyclic AMP, or cAMP. As the concentration of cAMP increases, it binds to a site in each subunit of the dimeric CAP protein, causing a conformational change that allows the protein to bind to the CAP site in the *lac* transcription-control region. The bound CAP-cAMP complex interacts with the polymerase bound to the promoter, greatly stimulating the rate of transcription initiation. This activation leads to synthesis of high levels of *lac* mRNA and subsequently of the enzymes encoded by the *lac* operon (Figure 7-3c).

In fact, the *lac* operon is more complex than depicted in the simplified model of Figure 7-3, parts (a)–(c). The tetrameric *lac* repressor actually binds to two sites simultaneously, one at the primary operator (*lacO1*) that overlaps the region of DNA bound by RNA polymerase at the promoter and at one of two secondary operators centered at +412 (*lacO2*) and -82 (*lacO3*) (Figure 7-3d). The *lac* repressor tetramer is a dimer of dimers. Each dimer binds to one operator. Simultaneous binding of the tetrameric *lac* repressor to the primary *lac* operator *O1* and one of the two secondary operators is possible because DNA is quite flexible, as we saw in the wrapping of DNA around the surface of a histone octamer in the nucleosomes of eukaryotes (Figure 6-29).

These secondary operators function to increase the local concentration of *lac* repressor in the micro-vicinity of the primary operator where repressor binding blocks RNA polymerase binding. Since the equilibrium of binding reactions depends on the concentrations of the binding partners, the resulting increased local concentration of *lac* repressor in the vicinity of *O*1 increases repressor binding to *O*1. There are approximately 10 *lac* repressor tetramers per *E. coli* cell. Because of binding to *O*2 and *O*3, there is nearly always a *lac* repressor tetramer much closer to *O*1 than would otherwise be the case if the 10 repressors were diffusing randomly through the cell. If both *O*2 and *O*3 are mutated so that the *lac* repressor no longer binds to them with high affinity, repression at the *lac* promoter is reduced by a factor of 70. Mutation of only *O*2 or only *O*3 reduces repression two-fold, indicating that either one of these secondary operators provides most of the stimulation of repression.

Although the promoters for different *E. coli* genes exhibit considerable homology, their exact sequences differ. The promoter sequence determines the intrinsic rate at which an RNA polymerase- σ complex initiates transcription of a gene in the absence of a repressor or activator protein. Promoters

that support a high rate of transcription initiation have -10 and -35 sequences similar to the ideal promoter shown previously and are called *strong promoters*. Those that support a low rate of transcription initiation differ from this ideal sequence and are called *weak promoters*. The *lac* operon, for instance, has a weak promoter. Its sequence differs from the consensus strong promoter at several positions. This low intrinsic rate of initiation is further reduced by the *lac* repressor and substantially increased by the cAMP-CAP activator.

Small Molecules Regulate Expression of Many Bacterial Genes via DNA-Binding Repressors and Activators

Transcription of most *E. coli* genes is regulated by processes similar to those described for the *lac* operon, although the detailed interactions differ at each promoter. The general mechanism involves a specific repressor that binds to the operator region of a gene or operon, thereby blocking transcription initiation. A small-molecule ligand (or ligands) binds to the repressor, controlling its DNA-binding activity and consequently the rate of transcription as appropriate for

TABLE 7-1 Sigma Factors of *E. coli*

Sigma Factor	Promoters Recognized	Promoter Consensus	
		-35 Region	-10 Region
σ^{70} (σ^D)	Housekeeping genes, most genes in exponentially replicating cells	TTGACA	TATAAT

SOURCES: T. M. Gruber and C. A. Gross, 2003, *Ann. Rev. Microbiol.* 57:441, S. L. McKnight and K. R. Yamamoto, eds., Cold Spring Harbor Laboratory Press; R. L. Gourse, W. Ross, and S. T. Rutherford, 2006, *J. Bacteriol.* 188:4627; U. K. Sharma and D. Chatterji, 2010, *FEMS Microbiol. Rev.* 34:646.

the needs of the cell. As for the *lac* operon, many eubacterial transcription-control regions contain one or more secondary operators that contribute to the level of repression.

Specific activator proteins, such as CAP in the *lac* operon, also control transcription of a subset of bacterial genes that have binding sites for the activator. Like CAP, other activators bind to DNA together with RNA polymerase, stimulating transcription from a specific promoter. The DNA-binding activity of an activator can be modulated in response to cellular needs by binding specific small-molecule ligands (e.g., cAMP) or by post-translational modifications, such as phosphorylation, that alter the conformation of the activator.

Transcription Initiation from Some Promoters Requires Alternative Sigma Factors

Most *E. coli* promoters interact with σ^{70} -RNA polymerase, the major initiating form of the bacterial enzyme. Transcription of certain groups of genes, however, is initiated by *E. coli* RNA polymerases containing one of several alternative sigma factors that recognize different consensus promoter sequences than σ^{70} does (Table 7-1). These alternative σ -factors are required for the transcription of sets of genes with related functions such as those involved in the response to heat shock or nutrient deprivation, motility, or sporulation in gram-positive eubacteria. In *E. coli* there are six alternative σ -factors in addition to the major “housekeeping” σ -factor, σ^{70} . The genome of the gram-positive, sporulating bacterium *Streptomyces coelicolor* encodes 63 σ -factors, the current record, based on sequence analysis of hundreds of eubacterial genomes. Most are structurally and functionally related to σ^{70} . But one class is unrelated, represented in *E. coli* by σ^{54} . Transcription initiation by RNA polymerases containing σ^{70} -like factors is regulated by repressors and activators that bind to DNA near the region where the polymerase binds, similar to initiation by σ^{70} -RNA polymerase itself.

Transcription by σ^{54} -RNA Polymerase Is Controlled by Activators That Bind Far from the Promoter

The sequence of one *E. coli* sigma factor, σ^{54} , is distinctly different from that of all the σ^{70} -like factors. Transcription of genes by RNA polymerases containing σ^{54} is regulated solely by activators whose binding sites in DNA, referred to as **enhancers**, generally are located 80–160 base pairs upstream from the start site. Even when enhancers are moved more than a kilobase away from a start site, σ^{54} -activators can activate transcription.

The best-characterized σ^{54} -activator—the NtrC protein (nitrogen regulatory protein C)—stimulates transcription of the *glnA* gene. *glnA* encodes the enzyme glutamine synthetase, which synthesizes the amino acid glutamine from glutamic acid and ammonia. The σ^{54} -RNA polymerase binds to the *glnA* promoter but does not melt the DNA strands and initiate transcription until it is activated by NtrC, a dimeric protein. NtrC, in turn, is regulated by a protein kinase called

NtrB. In response to low levels of glutamine, NtrB phosphorylates dimeric NtrC, which then binds to an enhancer upstream of the *glnA* promoter. Enhancer-bound phosphorylated NtrC then stimulates the σ^{54} -polymerase bound at the promoter to separate the DNA strands and initiate transcription.

Electron microscopy studies have shown that phosphorylated NtrC bound at enhancers and σ^{54} -polymerase bound at the promoter directly interact, forming a loop in the DNA between the binding sites (Figure 7-4). As discussed later in this chapter, this activation mechanism resembles the predominant mechanism of transcriptional activation in eukaryotes.

NtrC has ATPase activity, and ATP hydrolysis is required for activation of bound σ^{54} -polymerase by phosphorylated NtrC. Evidence for this is that mutants with an NtrC defective in ATP hydrolysis are invariably defective in stimulating the σ^{54} -polymerase to melt the DNA strands at the transcription start site. It is postulated that ATP hydrolysis supplies the energy required for melting the DNA strands. In contrast, the σ^{70} -polymerase does not require ATP hydrolysis to separate the strands at a start site.

Many Bacterial Responses Are Controlled by Two-Component Regulatory Systems

As we have just seen, control of the *E. coli glnA* gene depends on two proteins, NtrC and NtrB. Such two-component regulatory systems control many responses of bacteria to changes in their environment. At high concentrations of glutamine, glutamine binds to a sensor domain of NtrB, causing a conformational change in the protein that inhibits its histidine kinase activity (Figure 7-5a). At the same time, the regulatory domain of NtrC blocks the DNA-binding domain from binding the *glnA* enhancers. Under conditions of low glutamine, glutamine dissociates from the sensor domain in the NtrB protein, leading to activation of a histidine kinase *transmitter* domain in NtrB that transfers the γ -phosphate of ATP to a histidine residue (H) in the *transmitter* domain. This phosphohistidine then transfers the phosphate to an aspartic acid residue (D) in the NtrC protein. This causes a conformational change in NtrC that un masks the NtrC DNA-binding domain so that it can bind to the *glnA* enhancers.

Many other bacterial responses are regulated by two proteins with homology to NtrB and NtrC (Figure 7-5b). In each of these regulatory systems, one protein, called a *histidine kinase sensor*, contains a latent histidine kinase *transmitter* domain that is regulated in response to environmental changes detected by a sensor domain. When activated, the transmitter domain transfers the γ -phosphate of ATP to a histidine residue in the transmitter domain. The second protein, called a *response regulator*, contains a *receiver* domain homologous to the region of NtrC containing the aspartic acid residue that is phosphorylated by activated NtrB. The response regulator contains a second functional domain that is regulated by phosphorylation of the receiver domain. In many cases this domain of the response regulator is a sequence-specific DNA-binding domain that binds to related DNA sequences and functions either as a repressor, like the *lac*

EXPERIMENTAL FIGURE 7-4 DNA looping permits interaction of bound NtrC and σ^{54} -RNA polymerase. (a) Drawing (left) and electron micrograph (right) of DNA restriction fragment with phosphorylated NtrC dimers binding to the enhancer region near one end and σ^{54} -RNA polymerase bound to the *glnA* promoter near the other end.

repressor, or as an activator, like CAP or NtrC, regulating the transcription of specific genes. However, the effector domain can have other functions as well, such as controlling the direction in which the bacterium swims in response to a concentration gradient of nutrients. Although all transmitter domains are homologous (as are receiver domains), the transmitter domain of a specific sensor protein will phosphorylate only the receiver domains of specific response regulators, allowing specific responses to different environmental changes. Similar two-component histidyl-aspartyl phospho-relay regulatory systems are also found in plants.

Control of Transcription Elongation

In addition to regulation of transcription initiation by activators and repressors, expression of many bacterial operons is controlled by regulation of transcriptional elongation in the promoter-proximal region. This was first discovered in studies of *Trp* operon transcription in *E. coli* (Figure 4-13). *Trp* operon transcription is repressed by the Trp repressor when the concentration of tryptophan in the cytoplasm is high. But the low level of transcription initiation that still

occurs is further controlled by a process called *attenuation* when the concentration of charged $tRNA^{Trp}$ is sufficient to support a high rate of protein synthesis. The first 140 nt of the *Trp* operon does not encode proteins required for tryptophan biosynthesis, but rather consists of a leader sequence as diagrammed in Figure 7-6a. Region 1 of this leader sequence contains two successive Trp codons. Region 3 can base-pair with both regions 2 and 4. A ribosome follows closely behind the RNA polymerase, initiating translation of the leader peptide shortly after the 5' end of the *Trp* leader sequence emerges from the RNA polymerase. When the concentration of $tRNA^{Trp}$ is sufficient to support a high rate of protein synthesis, the ribosome translates through region 1 into region 2, blocking the ability of region 2 to base-pair with region 3 as it emerges from the surface of the transcribing RNA polymerase (Figure 7-6b, left). Instead, region 3 base-pairs with region 4 as soon as it emerges from the surface of the polymerase, forming an RNA hairpin (see Figure 4-9a) followed by several uracils, which is a signal for bacterial RNA polymerase to pause transcription and terminate. As a consequence, the remainder of the long *Trp* operon is not transcribed, and the cell does not waste energy required for

(a) Two-component system regulating response to low Gln

(b) General two-component signaling system

FIGURE 7-5 Two-component regulatory systems. At low cytoplasmic concentrations of glutamine, glutamine dissociates from NtrB, resulting in a conformational change that activates a protein kinase transmitter domain that transfers an ATP γ -phosphate to a conserved histidine (H) in the transmitter domain. This phosphate is then transferred to an aspartic acid (D) in the regulatory domain of the response regulator NtrC. This converts NtrC into its activated form, which binds the enhancer sites upstream of the *glnA* promoter (Figure 7-4). (b) General organization of two-component histidyl-aspartyl phospho-relay regulatory systems in bacteria and plants. [Adapted from A. H. West and A. M. Stock, 2001, *Trends Biochem. Sci.* **26**:369.]

its synthesis or for the translation of the encoded proteins when the concentration of tryptophan is high.

However, when the concentration of $tRNA^{Trp}$ is not sufficient to support a high rate of protein synthesis, the ribosome stalls at the two successive Trp codons in region 1 (Figure 7-6b, right). As a consequence, region 2 base-pairs with region 3 as soon as it emerges from the transcribing RNA polymerase. This prevents region 3 from base-pairing with region 4, so the 3-4 hairpin does not form and does not cause pausing by RNA polymerase or transcription termination. As a result, the proteins required for tryptophan synthesis are translated by ribosomes that initiate translation at the start codons for each of these proteins in the long polycistronic Trp mRNA.

Attenuation of transcription elongation also occurs at some operons and single genes encoding enzymes involved in the biosynthesis of other amino acids and metabolites through the function of *riboswitches*. Riboswitches form RNA tertiary structures that can bind small molecules when they are present at sufficiently high concentration. In some

FIGURE 7-6 Transcription control by regulation of RNA polymerase elongation and termination in the *E. coli* Trp operon.

(a) Diagram of the 140-nucleotide *trp* leader RNA. Colored regions are critical to the control of attenuation. (b) Translation of the *trp* leader sequence begins from the 5' end soon after it is synthesized, while synthesis of the rest of the polycistronic *trp* mRNA molecule continues.

At high concentrations of amino-acylated $tRNA^{Trp}$, formation of the 3-4 stem-loop followed by a series of Us causes termination of transcription. At low amino-acylated $tRNA^{Trp}$, region 3 is sequestered in the 2-3 stem-loop and cannot base-pair with region 4. In the absence of the stem-loop structure required for termination, transcription of the *trp* operon continues. [See C. Yanofsky, 1981, *Nature* **289**:751.]

cases this results in the formation of hairpin structures that lead to early termination of transcription as in the *Trp* operon. When the concentration of these small-molecule ligands is lower, the metabolites are not bound by the RNA and alternative RNA structures form that do not induce transcription termination. As discussed below, although the mechanism of transcriptional pausing and termination in eukaryotes is different, regulation of promoter-proximal transcriptional pausing and termination has recently been discovered to occur frequently in the regulation of gene expression in multicellular organisms as well.

KEY CONCEPTS of Section 7.1

Control of Gene Expression in Bacteria

- Gene expression in both prokaryotes and eukaryotes is regulated primarily by mechanisms that control the initiation of transcription.
- The first step in the initiation of transcription in *E. coli* is binding of the σ subunit complexed with an RNA polymerase to a promoter.
- The nucleotide sequence of a promoter determines its strength, that is, how frequently different RNA polymerase molecules can bind and initiate transcription per minute.
- Repressors are proteins that bind to operator sequences that overlap or lie adjacent to promoters. Binding of a repressor to an operator inhibits transcription initiation.
- The DNA-binding activity of most bacterial repressors is modulated by small-molecule ligands. This allows bacterial cells to regulate transcription of specific genes in response to changes in the concentration of various nutrients in the environment and metabolites in the cytoplasm.
- The *lac* operon and some other bacterial genes also are regulated by activator proteins that bind next to promoters and increase the rate of transcription initiation by interacting directly with RNA polymerase bound to an adjacent promoter.
- The major sigma factor in *E. coli* is σ^{70} , but several other, less abundant sigma factors are also found, each recognizing different consensus promoter sequences or interacting with different activators.
- Transcription initiation by all *E. coli* RNA polymerases, except those containing σ^{54} , can be regulated by repressors and activators that bind near the transcription start site (see Figure 7-3).
- Genes transcribed by σ^{54} -RNA polymerase are regulated by activators that bind to enhancers located ≈ 100 base pairs upstream from the start site. When the activator and σ^{54} -RNA polymerase interact, the DNA between their binding sites forms a loop (see Figure 7-4).
- In two-component regulatory systems, one protein acts as a sensor, monitoring the level of nutrients or other components in the environment. Under appropriate conditions, the

γ -phosphate of an ATP is transferred first to a histidine in the sensor protein and then to an aspartic acid in a second protein, the response regulator. The phosphorylated response regulator then performs a specific function in response to the stimulus, such as binding to DNA regulatory sequences, thereby stimulating or repressing transcription of specific genes (see Figure 7-5).

- Transcription in bacteria can also be regulated by controlling transcriptional elongation in the promoter-proximal region. This can be regulated by ribosome binding to the nascent mRNA as in the case of the *Trp* operon (Figure 7-6), or by riboswitches, RNA tertiary structures that bind small molecules, to determine whether a stem-loop followed by a string of uracils forms, causing the bacterial RNA polymerase to pause and terminate transcription.

7.2 Overview of Eukaryotic Gene Control

In bacteria, gene control serves mainly to allow a single cell to adjust to changes in its environment so that its growth and division can be optimized. In multicellular organisms, environmental changes also induce changes in gene expression. An example is the response to low oxygen (hypoxia) in which a specific set of genes is rapidly induced that helps the cell survive under the hypoxic conditions. These include secreted angiogenic proteins that stimulate the growth and penetration of new capillaries into the surrounding tissue. However, the most characteristic and biologically far-reaching purpose of gene control in multicellular organisms is execution of the genetic program that underlies embryological development. Generation of the many different cell types that collectively form a multicellular organism depends on the right genes being activated in the right cells at the right time during the developmental period.

In most cases, once a developmental step has been taken by a cell, it is not reversed. Thus these decisions are fundamentally different from the reversible activation and repression of bacterial genes in response to environmental conditions. In executing their genetic programs, many differentiated cells (e.g., skin cells, red blood cells, and antibody-producing cells) march down a pathway to final cell death, leaving no progeny behind. The fixed patterns of gene control leading to differentiation serve the needs of the whole organism and not the survival of an individual cell. Despite the differences in the purposes of gene control in bacteria and eukaryotes, two key features of transcription control first discovered in bacteria and described in the previous section also apply to eukaryotic cells. First, protein-binding regulatory DNA sequences, or control elements, are associated with genes. Second, specific proteins that bind to a gene's regulatory sequences determine where transcription will start and either activate or repress its transcription. A fundamental difference between transcription control in bacteria and eukaryotes is a consequence of the association of eukaryotic chromosomal DNA with histone octamers, forming nucleosomes that associate into chromatin fibers that

further associate into chromatin of varying degrees of condensation (Figures 6-29, 6-30, 6-32, and 6-33). Eukaryotic cells exploit chromatin structure to regulate transcription, a mechanism of transcription control that is not available to bacteria. As represented in Figure 7-2, in multicellular eukaryotes, many inactive genes are assembled into condensed chromatin, which inhibits the binding of RNA polymerases and general transcription factors required for transcription initiation. Activator proteins bind to control elements near the transcription start site of a gene as well as kilobases away and promote chromatin decondensation, binding of RNA polymerase to the promoter, and transcriptional elongation through chromatin. Repressor proteins bind to alternative control elements, causing condensation of chromatin and inhibition of polymerase binding or elongation. In this section, we discuss general principles of eukaryotic gene control and point out some similarities and differences between bacterial and eukaryotic systems. Subsequent sections of this chapter will address specific aspects of eukaryotic transcription in greater detail.

Regulatory Elements in Eukaryotic DNA Are Found Both Close to and Many Kilobases Away from Transcription Start Sites

Direct measurements of the transcription rates of multiple genes in different cell types have shown that regulation of transcription, either at the initiation step or during elongation away from the transcription start site, is the most widespread form of gene control in eukaryotes, as it is in bacteria. In eukaryotes, as in bacteria, a DNA sequence that specifies where RNA polymerase binds and initiates transcription of a gene is called a promoter. Transcription from a particular promoter is controlled by DNA-binding proteins that are functionally equivalent to bacterial repressors and activators. Recent results suggest that the intrinsic ability of the DNA sequence of a promoter region to associate with histone octamers also influences transcription. Since transcriptional regulatory proteins can often function either to activate or to repress transcription, depending on their association with other proteins, they are more generally called *transcription factors*. The DNA control elements in eukaryotic genomes that bind transcription factors often are located much farther from the promoter they regulate than is the case in prokaryotic genomes. In some cases, transcription factors that regulate expression of protein-coding genes in higher eukaryotes bind at regulatory sites tens of thousands of base pairs either **upstream** (opposite to the direction of transcription) or **downstream** (in the same direction as transcription) from the promoter. As a result of this arrangement, transcription of a single gene may be regulated by the binding of multiple different transcription factors to alternative control elements, directing expression of the same gene in different types of cells and at different times during development.

For example, several separate transcription-control DNA sequences regulate expression of the mammalian gene encoding the transcription factor *Pax6*. As mentioned earlier, *Pax6* protein is required for development of the eye. *Pax6* is also

required for the development of certain regions of the brain and spinal cord, and the cells in the pancreas that secrete hormones such as insulin. As also mentioned earlier, heterozygous humans with only one functional *Pax6* gene are born with *aniridia*, a lack of irises in the eyes (Figure 7-1a). The *Pax6* gene is expressed from at least three alternative promoters that function in different cell types and at different times during embryogenesis (Figure 7-7a).

Researchers often analyze gene control regions by preparing recombinant DNA molecules that can contain a fragment of DNA to be tested with the coding region for a **reporter gene** that is easy to assay. Typical reporter genes are luciferase, which generates light that can be assayed with great sensitivity and over many orders of magnitude of intensity using a luminometer. Other frequently used reporter genes encode a green fluorescent protein, which can be visualized by fluorescence microscopy (see Figures 9-8d and 9-15) and *E. coli* β -galactosidase, which generates an intensely blue insoluble precipitate when incubated with the colorless soluble lactose analog X-gal. When transgenic mice are prepared (see Figure 5-43) containing a β -galactosidase reporter gene fused to 8 kb of DNA upstream from *Pax6* exon 0, β -galactosidase is observed in the developing lens, cornea, and pancreas of the embryo halfway through gestation (Figure 7-7b). Analysis of transgenic mice with smaller fragments of DNA from this region allowed the mapping of separate transcription-control regions regulating transcription in the pancreas and in the lens and cornea. Transgenic mice with other reporter gene constructs revealed additional transcription-control regions (Figure 7-7a). These control transcription in the developing retina and different regions of the developing brain (encephalon). Some of these transcription-control regions are in introns between exons 4 and 5 and between exons 7 and 8. For example, a reporter gene under control of the region labeled *retina* in Figure 7-7a between exons 4 and 5 led to reporter gene expression specifically in the retina (Figure 7-7c).

Control regions for many genes are found several hundreds of kilobases away from the coding exons of the gene. One method for identifying such distant control regions is to compare the sequences of distantly related organisms. Transcription-control regions for a conserved gene are also often conserved and can be recognized in the background of a nonfunctional sequence that diverges during evolution. For example, there is a human DNA sequence ≈ 500 kilobases downstream of the *SALL1* gene that is highly conserved in mice, frogs, chickens, and fish (Figure 7-8a). *SALL1* encodes a transcription repressor required for normal development of the lower intestine, kidneys, limbs, and ears. When transgenic mice were generated containing this conserved DNA sequence linked to a β -galactosidase reporter gene (Figure 7-8b), the transgenic embryos expressed a very high level of the β -galactosidase reporter gene specifically in the developing limb buds (Figure 7-8c). Human patients with deletions in this region of the genome develop with limb abnormalities. These results indicate that this conserved region directs transcription of the *SALL1* gene in the developing limb. Presumably, other enhancers control expression of this gene in other

FIGURE 7-7 Analysis of transcription-control regions of the mouse *Pax6* gene in transgenic mice. (a) Three alternative *Pax6* promoters are utilized at distinct times during embryogenesis in different specific tissues of the developing embryo. Transcription-control regions regulating expression of *Pax6* in different tissues are indicated by colored rectangles. The telencephalon-specific control region in intron 1 between exons 0 and 1 has not been mapped to high resolution. The other control regions shown are ≈ 200 –500 base pairs in length. (b) β -galactosidase expressed in tissues of a mouse embryo with a β -galactosidase reporter transgene 10.5 days after fertilization. The genome of the mouse embryo contained a transgene with 8 kb of DNA upstream from exon 0 fused to the β -galactosidase coding region. Lens pit (LP) is the tissue that will develop into the lens of the eye. Expression was also observed in tissue that will develop into the pancreas (P). (c) β -galactosidase expression in a 13.5-day embryo with a β -galactosidase reporter gene under control of the sequence in part (a) between exons 4 and 5 marked Retina. Arrow points to nasal and temporal regions of the developing retina. *Pax6* transcription-control regions have also been found ≈ 17 kb downstream from the 3' exon in an intron of the neighboring gene. [Part (a) adapted from B. Kammendal et al., 1999, *Dev. Biol.* **205**:79. Parts (b) and (c) courtesy of Peter Gruss.]

types of cells, where it functions in the normal development of ears, the lower intestine, and kidneys. After discussing the proteins that carry out transcription in eukaryotic cells and eukaryotic promoters, we will return to a discussion of how such distant transcription-control regions, called **enhancers**, are thought to function.

Three Eukaryotic RNA Polymerases Catalyze Formation of Different RNAs

The nuclei of all eukaryotic cells examined so far (e.g., vertebrate, *Drosophila*, yeast, and plant cells) contain three different RNA polymerases, designated I, II, and III. These enzymes are eluted at different salt concentrations during ion-exchange chromatography, reflecting the polymerases' various net charges. The three polymerases also differ in their sensitivity to α -amanitin, a poisonous cyclic octapeptide produced by

some mushrooms (Figure 7-9). RNA polymerase I is insensitive to α -amanitin, but RNA polymerase II is very sensitive—the drug binds near the active site of the enzyme and inhibits translocation of the enzyme along the DNA template. RNA polymerase III has intermediate sensitivity.

Each eukaryotic RNA polymerase catalyzes transcription of genes encoding different classes of RNA (Table 7-2). *RNA polymerase I* (Pol I), located in the nucleolus, transcribes genes encoding precursor rRNA (**pre-rRNA**), which is processed into 28S, 5.8S, and 18S rRNAs. *RNA polymerase III* (Pol III) transcribes genes encoding tRNAs, 5S rRNA, and an array of small, stable RNAs, including one involved in RNA splicing (U6) and the RNA component of the signal-recognition particle (SRP) involved in directing nascent proteins to the endoplasmic reticulum (Chapter 13). *RNA polymerase II* (Pol II) transcribes all protein-coding genes; that is, it functions in production of mRNAs. RNA polymerase II also produces four of the five small nuclear RNAs that take part in RNA splicing and micro-RNAs (miRNAs) involved in translation control as well as the closely related endogenous small interfering RNAs (siRNAs) (see Chapter 8).

Each of the three eukaryotic RNA polymerases is more complex than *E. coli* RNA polymerase, although their structures are similar (Figure 7-10a, b). All three contain two large subunits and 10–14 smaller subunits, some of which are

(b) Mouse egg microinjection

EXPERIMENTAL FIGURE 7-8 The human *SALL1* gene enhancer activates expression of a reporter gene in limb buds of the developing mouse embryo.

(a) Graphic representation of the conservation of DNA sequence in a region of the human genome (from 50214–50220.5 kb of the chromosome 16 sequence) $\approx$ 500 kb downstream from the *SALL1* gene encoding a zinc-finger transcription repressor. A region of $\approx$ 500 bp of noncoding sequence is conserved from fish to human. Nine hundred base pairs including this conserved region were inserted into a plasmid next to the coding region for *E. coli* β -galactosidase. (b) The plasmid was microinjected into a pronucleus of a fertilized mouse egg and implanted in the uterus of a pseudo-pregnant mouse to generate a transgenic mouse embryo with the “reporter gene” on the injected plasmid incorporated into its genome (see Figure 5-43). (c) After 11.5 days of development, when limb buds develop, the fixed and permeabilized embryo was incubated in X-gal, which is converted by β -galactosidase into an insoluble, intensely blue compound. The $\approx$ 900-bp region of human DNA contained an enhancer that stimulated strong transcription of the β -galactosidase reporter gene in limb buds specifically. [From the VISTA Enhancer Browser, <http://enhancer.lbl.gov>. Parts (b) and (c) courtesy of Len A. Pennacchio, Joint Genome Institute, Lawrence Berkeley National Laboratory.]

common between two or all three of the polymerases. The best-characterized eukaryotic RNA polymerases are from the yeast *Saccharomyces cerevisiae*. Each of the yeast genes encoding the polymerase subunits has been subjected to gene-knockout mutations and the resulting phenotypes char-

acterized. In addition, the three-dimensional structure of yeast RNA polymerase II has been determined (Figure 7-10b, c). The three nuclear RNA polymerases from all eukaryotes so far examined are very similar to those of yeast. Plants contain two additional nuclear RNA polymerases (RNA polymerases IV and V), which are closely related to their RNA polymerase II but have a unique large subunit and some additional unique subunits. These function in transcriptional

EXPERIMENTAL FIGURE 7-9 Column chromatography separates and identifies the three eukaryotic RNA polymerases, each with its own sensitivity to α -amanitin.

A protein extract from the nuclei of cultured eukaryotic cells was passed through a DEAE Sephadex column and adsorbed protein eluted (black curve) with a solution of constantly increasing NaCl concentration. Fractions from the eluate were assayed for RNA polymerase activity (red curve). At a concentration of 1 μ g/ml, α -amanitin inhibits polymerase II activity but has no effect on polymerases I and III (green shading). Polymerase III is inhibited by 10 μ g/ml of α -amanitin, whereas polymerase I is unaffected even at this higher concentration. [See R. G. Roeder, 1974, *J. Biol. Chem.* **249**:241.]

TABLE 7-2 Classes of RNA Transcribed by the Three Eukaryotic Nuclear RNA Polymerases and Their Functions

Polymerase	RNA Transcribed	RNA Function
RNA polymerase I	Pre r-RNA (28S, 18S, 5.8S rRNAs)	Ribosome components, protein synthesis
RNA polymerase II	mRNA snRNAs siRNAs miRNAs	Encodes protein RNA splicing Chromatin-mediated repression, translation control Translation control
RNA polymerase III	tRNAs 5S rRNA snRNA U6 7S RNA Other stable short RNAs	Protein synthesis Ribosome component, protein synthesis RNA splicing Signal-recognition particle for insertion of polypeptides into the endoplasmic reticulum Various functions, unknown for many

repression directed by nuclear siRNAs in plants, discussed toward the end of this chapter.

The two large subunits of all three eukaryotic RNA polymerases (and RNA polymerases IV and V of plants) are related to each other and are similar to the *E. coli* β' and β

subunits, respectively (Figure 7-10). Each of the eukaryotic polymerases also contains an ω -like and two nonidentical α -like subunits (Figure 7-11). The extensive similarity in the structures of these core subunits in RNA polymerases from various sources indicates that this enzyme arose early in

(a) Bacterial RNA polymerase

(b) Yeast RNA polymerase II

(c) Yeast RNA polymerase II

FIGURE 7-10 Comparison of three-dimensional structures of bacterial and eukaryotic RNA polymerases. (a, b) These C_α trace models are based on x-ray crystallographic analysis of RNA polymerase from the bacterium *T. aquaticus* and core RNA polymerase II from *S. cerevisiae*. (a) The five subunits of the bacterial enzyme are distinguished by color. Only the N-terminal domains of the α subunits are included in this model. (b) Ten of the 12 subunits constituting yeast RNA polymerase II are shown in this model. Subunits that are similar in conformation to those in the bacterial enzyme are shown in the same colors. The C-terminal domain of the large subunit RPB1 was not observed in the crystal structure, but it is known to extend from the

position marked with a red arrow. (RPB is the abbreviation for "RNA polymerase B," which is an alternative way of referring to RNA polymerase II.) DNA entering the polymerases as they transcribe to the right is diagrammed. (c) Space-filling model of yeast RNA polymerase II including subunits 4 and 7. These subunits extend from the core portion of the enzyme shown in (b) near the region of the C-terminal domain of the large subunit. [Part (a) based on crystal structures from G. Zhang et al., 1999, *Cell* **98**:811. Part (b) adapted from P. Cramer et al., 2001, *Science* **292**:1863. Part (c) from K. J. Armache et al., 2003, *Proc. Nat'l Acad. Sci. USA* **100**:6964, and D. A. Bushnell and R. D. Kornberg, 2003, *Proc. Nat'l Acad. Sci. USA* **100**:6969.]

evolution and was largely conserved. This seems logical for an enzyme catalyzing a process so fundamental as copying RNA from DNA. In addition to their core subunits related to the *E. coli* RNA polymerase subunits, all three yeast RNA polymerases contain four additional small subunits, common to them but not to the bacterial RNA polymerase. Finally, each eukaryotic nuclear RNA polymerase has several enzyme-specific subunits that are not present in the other two nuclear RNA polymerases (Figure 7-11). Three of these additional subunits of Pol I and Pol III are homologous to the three additional Pol II-specific subunits. The other two Pol I-specific subunits are homologous to the Pol II general transcription factor TFIIF, discussed later, and the four additional subunits of Pol III are homologous to the Pol II general transcription factors TFIIF and TFIIE.

The clamp domain of RPB1 is so designated because it has been observed in two different positions in crystals of the free enzyme (Figure 7-12a) and a complex that mimics the elongating form of the enzyme (Figure 7-12b, c). This domain rotates on a hinge that is probably open when downstream DNA (dark blue template strand, cyan nontemplate strand) is inserted into this region of the polymerase, and then swings shut when the enzyme is in its elongation mode. RNA base-paired to the template strand is red in Figure 7-12b and c. It is postulated that when the 8–9 base-pair RNA-DNA hybrid region near the active site (Figure 7-12c) is bound between RPB1 and RPB2 and nascent RNA fills the exit channel, the clamp is locked in its closed position, anchoring the polymerase to the downstream double-stranded DNA. Also, a

FIGURE 7-11 Schematic representation of the subunit structure of the *E. coli* RNA core polymerase and yeast nuclear RNA polymerases. All three yeast polymerases have five core subunits homologous to the β , β' , two α , and ω subunits of *E. coli* RNA polymerase. The largest subunit (RPB1) of RNA polymerase II also contains an essential C-terminal domain (CTD). RNA polymerases I and III contain the same two nonidentical α -like subunits, whereas RNA polymerase II contains two other nonidentical α -like subunits. All three polymerases share the same ω -like subunit and four other common subunits. In addition, each yeast polymerase contains three to seven unique smaller subunits.

transcription elongation factor called DSIF, discussed later, associates with the elongating polymerase, holding the clamp in its closed conformation. As a consequence, the polymerase is extraordinarily processive, which is to say that it continues to polymerize ribonucleotides until it terminates transcription. After termination and RNA is released from the exit channel, the clamp can swing open, releasing the enzyme from the template DNA. This can explain how human RNA polymerase II can transcribe the longest human gene encoding dystrophin (DMD), which is ≈ 2 million base pairs in length, without dissociating and terminating transcription. Since transcription elongation proceeds at 1–2 kb per minute, transcription of the DMD gene requires approximately one day!

Gene-knockout experiments in yeast indicate that most of the subunits of the three nuclear RNA polymerases are essential for cell viability. Disruption of the few polymerase subunit genes that are not absolutely essential for viability (e.g., subunits 4 and 7 of RNA polymerase II) nevertheless results in very poorly growing cells. Thus, all the subunits are necessary for eukaryotic RNA polymerases to function normally. Archaea, like eubacteria, have a single type of RNA polymerase involved in gene transcription. But the archaeal RNA polymerases, like the eukaryotic nuclear RNA polymerases, have on the order of a dozen subunits. Archaea also have related general transcription factors, discussed later, consistent with their closer evolutionary relationship to eukaryotes than to eubacteria (Figure 1-1a).

The Largest Subunit in RNA Polymerase II Has an Essential Carboxyl-Terminal Repeat

The carboxyl end of the largest subunit of RNA polymerase II (RPB1) contains a stretch of seven amino acids that is nearly precisely repeated multiple times. Neither RNA polymerase I nor III contains these repeating units. This heptapeptide repeat, with a consensus sequence of Tyr-Ser-Pro-Thr-Ser-Pro-Ser, is known as the *carboxyl-terminal domain* (CTD) (Figure 7-10b, extending from the red arrow). Yeast RNA polymerase II contains 26 or more repeats, vertebrate enzymes have 52 repeats, and an intermediate number of repeats occur in RNA polymerase II from nearly all other eukaryotes. The CTD is critical for viability, and at least 10 copies of the repeat must be present for yeast to survive.

In vitro experiments with model promoters first showed that RNA polymerase II molecules that initiate transcription

FIGURE 7-12 The clamp domain of RPB1. The structures of the free (a) and transcribing (b) RNA polymerase II differ mainly in the position of a clamp domain in RPB1 (orange), which swings over the cleft between the jaws of the polymerase during formation of the transcribing complex, trapping the template DNA strand and transcript. Binding of the clamp domain to the 8–9-base-pair RNA–DNA hybrid may help couple clamp closure to the presence of RNA, stabilizing the closed, elongating complex. RNA is shown in red, the template DNA strand in dark blue, and the downstream nontemplate DNA strand in cyan in this model of an elongating complex. (c) The clamp closes over the incoming downstream DNA. This model is shown with portions of RPB2 that form one side of the cleft removed so that the nucleic acids can be better visualized. The Mg^{2+} ion that participates in catalysis of

phosphodiester bond formation is shown in green. Wall is the domain of RPB2 that forces the template DNA entering the jaws of the polymerase to bend before it exits the polymerase. The bridge α helix shown in green extends across the cleft in the polymerase (see Figure 7-10b) and is postulated to bend and straighten as the polymerase translocates one base down the template strand. The nontemplate strand is thought to form a flexible single-stranded region above the cleft (not shown) extending from three bases downstream of the template base-paired to the 3' base of the growing RNA and extending to the template strand as it exits the polymerase, where it hybridizes with the template strand to generate the transcription bubble. [Adapted from A. L. Gnatt et al., 2001, *Science* **292**:1876.]

have an unphosphorylated CTD. Once the polymerase initiates transcription and begins to move away from the promoter, many of the serine and some tyrosine residues in the CTD are phosphorylated. Analysis of polytene chromosomes from *Drosophila* salivary glands prepared just before molting of the larva, a time of active transcription, indicate that the CTD also is phosphorylated during in vivo tran-

scription. The large chromosomal “puffs” induced at this time in development are regions where the genome is very actively transcribed. Staining with antibodies specific for the phosphorylated or unphosphorylated CTD demonstrated that RNA polymerase II associated with the highly transcribed puffed regions contains a phosphorylated CTD (Figure 7-13).

EXPERIMENTAL FIGURE 7-13 Antibody staining demonstrates that the carboxyl-terminal domain (CTD) of RNA polymerase II is phosphorylated during in vivo transcription.

Salivary-gland polytene chromosomes were prepared from *Drosophila* larvae just before molting. The preparation was treated with a rabbit antibody specific for phosphorylated CTD and with a goat antibody specific for unphosphorylated CTD. The preparation then was stained with fluorescein-labeled anti-goat antibody (green) and rhodamine-labeled anti-rabbit antibody (red). Thus polymerase molecules with an unphosphorylated CTD stain green, and those with a phosphorylated CTD stain red. The molting hormone ecdysone induces very high rates of transcription in the puffed regions labeled 74EF and 75B; note that only phosphorylated CTD is present in these regions. Smaller puffed regions transcribed at high rates also are visible. Nonpuffed sites that stain red (up arrow) or green (horizontal arrow) also are indicated, as is a site staining both red and green, producing a yellow color (down arrow). [From J. R. Weeks et al., 1993, *Genes Dev.* **7**:2329; courtesy of J. R. Weeks and A. L. Greenleaf.]

KEY CONCEPTS of Section 7.2

Overview of Eukaryotic Gene Control

- The primary purpose of gene control in multicellular organisms is the execution of precise developmental decisions so that the proper genes are expressed in the proper cells during embryologic development and cellular differentiation.
- Transcriptional control is the primary means of regulating gene expression in eukaryotes, as it is in bacteria.
- In eukaryotic genomes, DNA transcription-control elements may be located many kilobases away from the promoter they regulate. Different control regions can control transcription of the same gene in different cell types.
- Eukaryotes contain three types of nuclear RNA polymerases. All three contain two large and three smaller core subunits with homology to the β' , β , α , and ω subunits of *E. coli* RNA polymerase, as well as several additional small subunits (see Figure 7-11).
- RNA polymerase I synthesizes only pre-rRNA. RNA polymerase II synthesizes mRNAs, some of the small nuclear RNAs that participate in mRNA splicing, micro-RNAs (miRNAs) that regulate translation of complementary mRNAs, and small interfering RNAs (siRNAs) that regulate the stability of complementary mRNAs. RNA polymerase III synthesizes rRNAs, 5S rRNA, and several other relatively short, stable RNAs (see Table 7-2).
- The carboxyl-terminal domain (CTD) in the largest subunit of RNA polymerase II becomes phosphorylated during transcription initiation and remains phosphorylated as the enzyme transcribes the template.

7.3 RNA Polymerase II Promoters and General Transcription Factors

The mechanisms that regulate transcription initiation and elongation by RNA polymerase II have been studied extensively, because this is the polymerase that transcribes mRNAs. Transcription initiation and elongation by RNA polymerase II are the initial biochemical processes required for the expression of protein-coding genes and are the steps in gene expression that are most frequently regulated to determine when and in which cells specific proteins are synthesized. As noted in the previous section, expression of eukaryotic protein-coding genes is regulated by multiple protein-binding DNA sequences, generically referred to as transcription-control regions. These include promoters, which determine where transcription of the DNA template begins, and other types of control elements located near transcription start sites as well as sequences located far from the genes they regulate, which control the type of cell in which the gene is transcribed and how frequently it is transcribed. In this section, we take a closer look at the properties of various control elements

found in eukaryotic protein-coding genes and some techniques used to identify them.

RNA Polymerase II Initiates Transcription at DNA Sequences Corresponding to the 5' Cap of mRNAs

In vitro transcription experiments using purified RNA polymerase II, a protein extract prepared from the nuclei of cultured cells, and DNA templates containing sequences encoding the 5' ends of mRNAs for a number of abundantly expressed genes revealed that the transcripts produced always contained a cap structure at their 5' ends identical with that present at the 5' end of the spliced mRNA expressed from the gene (see Figure 4-14). In these experiments, the 5' cap was added to the 5' end of the nascent RNA by enzymes in the nuclear extract, which can only add a cap to an RNA that has a 5' tri- or diphosphate. Because a 5' end generated by cleavage of a longer RNA would have a 5' monophosphate, it would not be capped. Consequently, researchers concluded that the capped nucleotides generated in the in vitro transcription reactions must have been the nucleotides with which transcription was initiated. Sequence analysis revealed that, for a given gene, the sequence at the 5' end of the RNA transcripts produced in vitro is the same as that at the 5' end of the mRNAs isolated from cells, confirming that the capped nucleotide of eukaryotic mRNAs coincides with the transcription start site. Today, the transcription start site for a newly characterized mRNA generally is determined simply by identifying the DNA sequence encoding the 5'-capped nucleotide of the encoded mRNA.

The TATA Box, Initiators, and CpG Islands Function as Promoters in Eukaryotic DNA

Several different DNA sequences can function as promoters for RNA polymerase II, directing the polymerase where to initiate transcription of an RNA complementary to the template strand of a double-stranded DNA. These include TATA boxes, initiators, and CpG islands.

TATA Boxes The first genes to be sequenced and studied through in vitro transcription systems were viral genes and cellular protein-coding genes that are very actively transcribed either at particular times of the cell cycle or in specific differentiated cell types. In all these highly transcribed genes, a conserved sequence called the **TATA box** was found ≈ 26 – 31 base pairs upstream of the transcription start site (Figure 7-14). Mutagenesis studies have shown that a single-base change in this nucleotide sequence drastically decreases in vitro transcription by RNA polymerase II of genes adjacent to a TATA box. If the base pairs between the TATA box and the normal transcription start site are deleted, transcription of the altered, shortened template begins at a new site ≈ 25 base pairs downstream from the TATA box. Consequently, the TATA box acts similarly to an *E. coli* promoter

FIGURE 7-14 Core promoter elements of non-CpG island promoters in metazoans. The sequence of the strand with the 5' end at the left and the 3' end at the right is shown. The most frequently observed bases in TATA-box promoters are shown in larger font. A⁺ is the base at which transcription starts, Y is a pyrimidine (C or T), N is any of the four bases. [Adapted from S. T. Smale and J. T. Kadonaga, 2003, *Ann. Rev. Biochem.* 72:449.]

to position RNA polymerase II for transcription initiation (see Figure 4-12).

Initiator Sequences Instead of a TATA box, some eukaryotic genes contain an alternative promoter element called an *initiator*. Most naturally occurring initiator elements have a cytosine (C) at the -1 position and an adenine (A) residue at the transcription start site (+1). Directed mutagenesis of mammalian genes with an initiator-containing promoter revealed that the nucleotide sequence immediately surrounding the start site determines the strength of such promoters. Unlike the conserved TATA box sequence, however, only an extremely degenerate initiator consensus sequence has been defined:

where A⁺ is the base at which transcription starts, Y is a pyrimidine (C or T), N is any of the four bases, and T/A is T or A at position +3. As we shall see after discussing general transcription factors required for RNA polymerase II initiation, other specific DNA sequences designated BRE and DPE can be bound by these proteins and influence promoter strength (Figure 7-14).

CpG Islands Transcription of genes with promoters containing a TATA box or initiator element begins at a well-defined initiation site. However, transcription of most protein-coding genes in mammals (≈60–70 percent) occurs at a lower rate than TATA box and Initiator-containing promoters, and initiates at several alternative start sites within regions of ≈100–1000 base pairs that have an unusually high frequency of CG sequences. Such genes often encode proteins that are not required in large numbers (e.g., enzymes involved in basic metabolic processes required in all cells, often called “housekeeping genes”). These promoter regions are called **CpG islands** (where “p” represents the phosphate between the C and G nucleotides) because they occur relatively rarely in the genome sequence of mammals.

In mammals, most Cs followed by a G that are not associated with CpG island promoters are methylated at position 5 of the pyrimidine ring (5-methyl C, represented C^{Me}; see Figure 2-17). CG sequences are thought to be underrepresented in mammalian genomes because spontaneous deamination of 5-methyl C generates thymidine. Over the time scale of mammalian evolution, this is thought to have led to the conversion of most CGs to TG by DNA-repair mechanisms. As a consequence, the frequency of CG in the human genome is only 21 percent of the expected frequency if Cs were randomly followed by a G. However, the Cs in active CpG island promoters are unmethylated. Consequently, when they deaminate spontaneously, they are converted to U, a base that is recognized by DNA repair enzymes and converted back to C. As a result, the frequency of CG sequences in CpG island promoters is close to that expected if C were followed by any of the other three nucleotides randomly.

CG-rich sequences are bound by histone octamers more weakly than CG-poor sequences because more energy is required to bend them into the small-diameter loops required to wrap around the histone octamer forming a nucleosome (Figure 6-29). As a consequence, CpG islands coincide with nucleosome-free regions of DNA. Much remains to be learned about the molecular mechanisms that control transcription from CpG island promoters, but a current hypothesis is that the general transcription factors discussed in the next section can bind to them because CpG islands exclude nucleosomes.

Divergent Transcription from CpG Island Promoters Another remarkable feature of CpG islands is that transcription is initiated in both directions, even though only transcription of the sense strand yields an mRNA. By a mechanism(s) that remains to be elucidated, most RNA polymerase II molecules transcribing in the “wrong” direction, i.e., transcribing the non-sense strand, pause or terminate by ≈1 kb from the transcription start site. This was discovered by taking advantage of the stability of the elongation complex, presumably conferred by the RNA polymerase II clamp domain when an RNA-DNA hybrid is bound near the active site (Figure 7-12b, c).

Nuclei were isolated from cultured human cells and incubated in a buffered solution containing a concentration of salt and mild detergent that removes RNA polymerases except for those in the process of elongation because of their stable association with template DNA. Nucleotide triphosphates were then added with UTP substituted by bromo-UTP containing uracil with a Br atom at the 5 position on the pyrimidine ring (Figure 2-17). The nuclei were then incubated at 37 °C long enough for ≈100 nucleotides to be polymerized by the RNA polymerase II (Pol II) molecules that were in the process of transcription elongation at the time the nuclei were isolated. RNA was then isolated and RNA containing bromo-U was immunoprecipitated with antibody specific for RNA labeled with bromo-U. Thirty-three nucleotides at the 5' ends of these RNAs were then sequenced by massively parallel DNA sequencing of reverse transcripts, and the sequences were mapped on the human genome.

EXPERIMENTAL FIGURE 7-15 Analysis of elongating RNA polymerase II molecules in human fibroblasts. Nuclei from cultured fibroblasts were isolated and incubated in a buffer with a nonionic detergent that prevents RNA polymerase II from initiating transcription. Treated nuclei were incubated with ATP, CTP, GTP, and Br-UTP for 5 minutes at 30 °C, a time sufficient to incorporate ≈ 100 nucleotides. RNA was then isolated and fragmented to ≈ 100 nucleotides by controlled incubation at high pH. Specific RNA oligonucleotides were ligated to the 5' and 3' ends of the RNA fragments, which were then subjected to reverse transcription. The resulting DNA was amplified by polymerase chain reaction and subjected to massively parallel DNA sequencing. The sequences determined were aligned to the transcription start sites (TSS) of all known human genes and the number of sequence reads per kilobase of total sequenced DNA was plotted for 10 base-pair intervals of sense transcripts (red) and antisense transcripts (blue). See text for discussion. [From L. J. Core, J. J. Waterfall, and J. T. Lis, 2008, *Science* **322**:1845.]

Figure 7-15 shows a plot of the number of sequence reads per kilobase of total BrU-labeled RNA relative to the major transcription start sites (TSS) of all currently known human protein-coding genes. The results show that approximately equal numbers of RNA polymerase molecules transcribed most promoters (mostly CpG island promoters) in both the sense direction (red, plotted upward to indicate transcription in the sense direction) and the antisense direction (blue, plotted downward to represent transcription in the opposite, antisense direction). A peak of sense transcripts was observed at $\approx +50$ relative to the major transcription start site (TSS), indicating that Pol II pauses in the $+50$ to $+250$ region before elongating further. A peak at -250 to -500 relative to the major sense transcription start site of Pol II transcribing in the antisense direction also was observed, revealing paused RNA polymerase II molecules at the other end of the nucleosome-free regions in CpG island promoters. Note that the number of sequence reads, and therefore the number of elongating polymerases, is lower for polymerases transcribing in the antisense direction more than 1 kb from the transcription start compared to polymerases transcribing more than 1 kb from the transcription start site in the sense direction. The molecular mechanism(s) accounting for this difference is currently an intense area of investigation. Note that a low number of sequence reads was also observed transcribing in the “wrong” direction upstream of the major transcription start sites (red

sequences reads to the left of 0 and blue sequence reads to the right of 0), indicating that there is a low level of transcription from seemingly random sites throughout the genome. These recent discoveries of divergent transcription from CpG island promoters and low-level transcription of most of the genomes of eukaryotes have been a great surprise to most researchers.

Chromatin Immunoprecipitation The technique of chromatin immunoprecipitation outlined in Figure 7-16a provided additional data supporting the occurrence of divergent transcription from most CpG island promoters in mammals. The data from this analysis are reported as the number of times a specific sequence from this region of the genome was identified per million total sequences analyzed (Figure 7-16b). At divergently transcribed genes, such as the *Hsd17b12* gene encoding an enzyme involved in intermediary metabolism, two peaks of immunoprecipitated DNA were detected, corresponding to Pol II transcribing in the sense and antisense directions. However, Pol II was only detected >1 kb from the start site in the sense direction. The number of counts per million from this region of the genome was very low because the gene is transcribed at low frequency. However, the number of counts per million at the start-site regions for both sense and antisense transcription was much higher, reflecting the fact that Pol II molecules had initiated transcription in both directions at this promoter, but paused before transcribing >500 base pairs from the start sites in each direction. In contrast, the *Rpl6* gene encoding a large ribosomal subunit protein that was abundantly transcribed in these proliferating cells was transcribed almost exclusively in the sense direction. The number of sequence counts per million >1 kb downstream from the transcription start site was much higher, reflecting the high rate of transcription of this gene.

Transcription start-site-associated RNAs (TSSa RNAs, red and blue arrowheads at the bottom of Figure 7-16b) represent sequences of short RNAs isolated from these cells, thought to result from degradation of nascent RNAs released from paused Pol II molecules that terminate. Note that they include transcripts of both the sense (blue arrows) and antisense (red arrows) from the divergently transcribed gene, whereas only sense TSSa RNAs were found for the unidirectionally transcribed gene. The observation of these TSSa RNAs from CpG island promoters further support the conclusion that they are transcribed in both directions.

General Transcription Factors Position RNA Polymerase II at Start Sites and Assist in Initiation

Initiation by RNA polymerase II requires several initiation factors. These initiation factors position Pol II molecules at transcription start sites and help to separate the DNA strands so that the template strand can enter the active site of the enzyme. They are called *general transcription factors* because they are required at most, if not all, promoters transcribed by RNA polymerase II. These proteins are designated

EXPERIMENTAL FIGURE 7-16 Chromatin immunoprecipitation technique. (a) Step **1**: Live cultured cells or tissues are incubated in 1% formaldehyde to covalently cross-link protein to DNA and proteins to proteins. Step **2**: The preparation is then subjected to sonication to solubilize and shear chromatin to fragments of 200 to 500 base pairs of DNA. Step **3**: An antibody to a protein of interest, here RNA polymerase II, is added, and DNA covalently linked to the protein of interest is immunoprecipitated. Step **4**: The covalent cross-linking is then reversed and DNA is isolated. The isolated DNA can be analyzed by polymerase chain reaction with primers for a sequence of interest. Alternatively, total recovered DNA can be amplified, labeled by incorporation of a fluorescently labeled nucleotide, and hybridized to a microarray (Figure 5-29) or subjected to massively parallel DNA

sequencing. (b) Results from DNA sequencing of chromatin from mouse embryonic stem cells immunoprecipitated with antibody to RNA polymerase II are shown for a gene that is divergently transcribed (left) and a gene that is transcribed only in the sense direction (right). Data are plotted as the number of times a DNA sequence in a 50-base-pair interval was observed per million base pairs sequenced. The region encoding the 5' end of the gene is shown below, with exons shown as rectangles and introns as lines. TSSa RNAs (red and blue arrowheads) represent RNAs of ≈ 20 –50 nucleotides that were isolated from the same cells. Blue indicates RNAs transcribed in the sense direction, and red indicates RNAs transcribed in the antisense direction. [Part (a), see A. Hecht and M. Grunstein, 1999, *Methods Enzymol.* **304**:399. Part (b) adapted from P. B. Rahl et al., 2010, *Cell* **141**:432.]

TFIIA, TFIIB, etc., and most are multimeric proteins. The largest is TFIID, which consists of a single 38-kDa TATA box binding protein (TBP) and 13 TBP-associated factors (TAFs). General transcription factors with similar activities and homologous sequences are found in all eukaryotes. The complex of Pol II and its general transcription factors bound

to a promoter and ready to initiate transcription is called a *preinitiation complex*. Figure 7-17 summarizes the stepwise assembly of the Pol II transcription preinitiation complex in vitro on a promoter containing a TATA box. The TBP subunit of TFIID rather than the intact TFIID complex was used in the studies that revealed the order of general transcription

FIGURE 7-17 In vitro assembly of RNA polymerase II preinitiation complex. The indicated general transcription factors and purified RNA polymerase II (Pol II) bind sequentially to TATA-box DNA to form a preinitiation complex. ATP hydrolysis then provides the energy for unwinding of DNA at the start site by a TFIIF subunit. As Pol II initiates transcription in the resulting open complex, the polymerase moves away from the promoter and its CTD becomes phosphorylated. In vitro, the general transcription factors (except for TBP) dissociate from the TBP-promoter complex, but it is not yet known which factors remain associated with promoter regions following each round of transcription initiation in vivo.

factor and RNA polymerase II assembly because it can be expressed at a high level in *E. coli* and readily purified, while intact TFIID is difficult to purify from eukaryotic cells.

TBP is the first protein to bind to a TATA box promoter. All eukaryotic TBPs analyzed to date have very similar C-terminal domains of 180 residues. This domain of TBP folds into a saddle-shaped structure; the two halves of the molecule exhibit an overall dyad symmetry but are not identical. TBP interacts with the minor groove in DNA, bending the helix considerably (see Figure 4-5). The DNA-binding surface of TBP is conserved in all eukaryotes, explaining the high conservation of the TATA box promoter element (see Figure 7-14).

Once TBP has bound to the TATA box, TFIIB can bind. TFIIB is a monomeric protein, slightly smaller than TBP. The C-terminal domain of TFIIB makes contact with both TBP and DNA on either side of the TATA box. During transcription initiation, its N-terminal domain is inserted into the RNA exit channel of RNA polymerase II (see Figure 7-10). The TFIIB N-terminal domain assists Pol II in melting the DNA strands at the transcription start site and interacts with the template strand near the Pol II active site. Following TFIIB binding, a preformed complex of TFIIF (a heterodimer of two different subunits in mammals) and Pol II binds, positioning the polymerase over the start site. Two more general transcription factors must bind before the DNA duplex can be separated to expose the template strand. First to bind is tetrameric TFIIE comprised of two copies each of two different subunits. TFIIE creates a docking site for TFIIH, another multimeric factor containing 10 different subunits. Binding of TFIIH completes assembly of the transcription preinitiation complex in vitro (Figure 7-17). Figure 7-18 shows a current model for the structure of a preinitiation complex.

The helicase activity of one of the TFIIH subunits uses energy from ATP hydrolysis to help unwind the DNA duplex at the start site, allowing Pol II to form an *open complex* in which the DNA duplex surrounding the start site is melted and the template strand is bound at the polymerase active site. Figure 7-19 shows molecular models based on x-ray crystallography of the complex of TBP (purple), TFIIB (red), and Pol II (gold) associated with promoter DNA before the strands near the transcription start site are separated

FIGURE 7-18 Model for the structure of an RNA polymerase II preinitiation complex. Yeast RNA polymerase II is shown as a space-filling model with the direction of transcription to the right. The template strand of DNA is shown in dark blue and the nontemplate strand in cyan. The start site of transcription is shown as a space-filling cyan and dark blue base pair. TBP and TFIIB are shown as purple and red worm traces of the polypeptide backbone. Structures for TFII E, F, and H have not been determined to high resolution. Their approximate positions lying over the DNA in the preinitiation complex are shown by ellipses for TFII E (green), TFII F (violet), and TFII H (light blue). [Adapted from G. Miller and S. Hahn, 2006, *Nat. Struct. Biol.* **13**:603.]

(closed complex, Figure 7-19a) and after the strands are separated and the template strand enters the Pol II-TFIIB complex, placing the transcription start site (+1) at the active site (open complex, Figure 7-19b). A Mg^{2+} ion bound at the active site of Pol II assists in catalysis of phosphodiester bond synthesis. If all the ribonucleoside triphosphates are present, Pol II begins transcribing the template strand.

As the polymerase transcribes away from the promoter region, the N-terminal domain of TFIIB is released from the RNA exit channel as the 5' end of the nascent RNA enters it. A subunit of TFIIH phosphorylates the Pol II CTD multiple times on the serine 5 (underlined) of the Tyr-Ser-Pro-Thr-

Ser-Pro-Ser repeat that comprises the CTD. As we shall discuss further in Chapter 8, the CTD that is multiply phosphorylated on serine 5 is a docking site for the enzymes that form the cap structure (Figure 4-14) on the 5' end of RNAs transcribed by RNA polymerase II. In the minimal in vitro transcription

(a) Closed complex

(b) Open complex

FIGURE 7-19 Models for the closed and open complexes of promoter DNA in complex with TBP, TFIIB, and Pol II based on x-ray crystallography. Pol II is shown in tan, TBP in purple, TFIIB in red, the DNA template strand in dark blue, and the DNA nontemplate strand in cyan. The base encoding the transcription start site (+1) is shown as space-filling. The B-linker region of TFIIB interacts with DNA

in the closed complex (a), where the strands are initially separated (point of DNA opening). The Mg^{2+} ion at the active site is shown as a green sphere. The nontemplate strand of the transcription bubble in the open complex (b) is not visualized in crystal structures of models of the open complex because it has alternative conformations in different complexes. [Adapted from D. Kostrewa et al., 2009, *Nature* **462**:323.]

assay containing only these general transcription factors and purified RNA polymerase II, TBP remains bound to the TATA box as the polymerase transcribes away from the promoter region, but the other general transcription factors dissociate.

 Remarkably, the first subunits of TFIIF to be cloned from humans were identified because mutations in them cause defects in the repair of damaged DNA. In normal individuals, when a transcribing RNA polymerase becomes stalled at a region of damaged template DNA, a subcomplex composed of several subunits of TFIIF, including the helicase subunit mentioned above, recognizes the stalled polymerase and then associates with other proteins that function with TFIIF in repairing the damaged DNA region. In patients with mutant forms of these TFIIF subunits, such repair of damaged DNA in transcriptionally active genes is impaired. As a result, affected individuals have extreme skin sensitivity to sunlight (a common cause of DNA damage is ultraviolet light) and exhibit a high incidence of cancer. Consequently, these subunits of TFIIF serve two functions in the cell, one in the process of transcription initiation and a second function in the repair of DNA. Depending on the severity of the defect in TFIIF function, these individuals may suffer from diseases such as xeroderma pigmentosum and Cockayne's syndrome (Chapter 24). ■

In Vivo Transcription Initiation by RNA Polymerase II Requires Additional Proteins

Although the general transcription factors discussed above allow RNA polymerase to initiate transcription *in vitro*, another general transcription factor, TFIIA, is required for initiation by Pol II *in vivo*. Purified TFIIA forms a complex with TBP and TATA box DNA. X-ray crystallography of this complex shows that TFIIA interacts with the side of TBP that is upstream from the direction of transcription on promoters containing a TATA box. In metazoans (multicellular animals), TFIIA and TFIID, with its multiple TAF subunits, bind first to TATA box DNA, and then the other general transcription factors subsequently bind as indicated in Figure 7-17.

The TAF subunits of TFIID function in initiating transcription from promoters that lack a TATA box. For instance, some TAF subunits contact the initiator element in promoters where it occurs, probably explaining how such sequences can replace a TATA box. Additional TFIID TAF subunits can bind to a consensus sequence A/G-G-A/T-C/T-G/A/C centered ≈ 30 base pairs downstream from the transcription start site in many genes that lack a TATA box promoter. Because of its position, this regulatory sequence is called the *downstream promoter element (DPE)* (Figure 7-14). The DPE facilitates transcription of TATA-less genes that contain it by increasing TFIID binding. Also, an α helix of TFIIB binds to the major groove of DNA upstream of the TATA-box (see Figure 7-19), and the strongest promoters contain the optimal sequence for this interaction, the BRE shown in Figure 7-14.

Chromatin immunoprecipitation assays (Figure 7-16) using antibodies to TBP show that it binds in the region between the sense and antisense transcription start sites in CpG island promoters. Consequently, the same general transcription factors probably are required for initiation from the weaker CpG island promoters as from promoters containing a TATA box. The absence of the promoter elements summarized in Figure 7-14 may account for the divergent transcription from multiple transcription start sites observed from these promoters, since cues from the DNA sequence are not present to orient the preinitiation complex. TFIID and the other general transcription factors may choose among alternative, nearly equivalent weak binding sites in this class of promoters, potentially explaining the low frequency of transcription initiation as well as the alternative transcription start sites in divergent directions generally observed from CpG island promoters.

Elongation Factors Regulate the Initial Stages of Transcription in the Promoter-Proximal Region

In metazoans, at most promoters, Pol II pauses after transcribing ≈ 20 –50 nucleotides, due to the binding of a five-subunit protein called NELF (*negative elongation factor*). This is followed by the binding of a two-subunit elongation factor called DSIF (*DRB sensitivity-inducing factor*), so named because an ATP analog called DRB inhibits further transcription elongation in its presence. The inhibition of Pol II elongation that results from NELF binding is relieved when DSIF, NELF, and serine 2 of the Pol II CTD repeat (Tyr-Ser-Pro-Thr-Ser-Pro-Ser) are phosphorylated by a protein kinase with two subunits, CDK9-cyclin T, also called P-TEFb, which associates with the Pol II, NELF, DSIF complex. The same elongation factors regulate transcription from CpG island promoters. These factors that regulate elongation in the promoter-proximal region provide a mechanism for controlling gene transcription in addition to the regulation of transcription initiation. This overall strategy for regulating transcription at both the steps of initiation and elongation in the promoter-proximal region is similar to the regulation of the *Trp* operon in *E. coli* (Figure 7-6), although the molecular mechanisms involved are distinct.

 Transcription of HIV (human immunodeficiency virus), the cause of AIDS, is dependent on the activation of CDK9-cyclin T by a small viral protein called Tat. Cells infected with *tat*⁻ mutants produce short viral transcripts ≈ 50 nucleotides long. In contrast, cells infected with wild-type HIV synthesize long viral transcripts that extend throughout the integrated proviral genome (see Figure 4-49 and Figure 6-13). Thus Tat protein functions as an *antitermination factor*, permitting RNA polymerase II to read through a transcriptional block. (Tat is initially made by rare transcripts that fail to terminate when the HIV promoter is transcribed at high rate in “activated” T-lymphocytes, one type of white blood cell; see Chapter 23). Tat is a sequence-specific RNA-binding protein. It binds to the RNA copy of a sequence called TAR, which forms a stem-loop structure near the 5' end

FIGURE 7-20 Model of antitermination complex composed of HIV Tat protein and several cellular proteins. The TAR element in the HIV transcript contains sequences recognized by Tat and the cellular protein cyclin T. Cyclin T activates and helps position the protein kinase CDK9 near its substrate, the CTD of RNA polymerase II. CTD phosphorylation at serine 2 of the Pol II CTD heptad repeat is required for transcription elongation. Cellular proteins DSIF (also called Spt4/5) and the NELF complex are also involved in regulating Pol II elongation, as discussed in the text. [See P. Wei et al., 1998, *Cell* **92**:451; T. Wada et al., 1998, *Genes Dev.* **12**:357; and Y. Yamaguchi et al., 1999, *Cell* **97**:41.]

of the HIV transcript (Figure 7-20). TAR also binds cyclin T, holding the CDK9-cyclin T complex close to the polymerase, where it efficiently phosphorylates its substrates, resulting in transcription elongation. Chromatin immunoprecipitation assays done after treating cells with specific inhibitors of CDK9 indicate that the transcription of ≈ 30 percent of mammalian genes is regulated by controlling the activity of CDK9-cyclin T (P-TEFb), although this is probably done most frequently by sequence-specific DNA-binding transcription factors rather than an RNA-binding protein, as in the case of HIV Tat. ■

KEY CONCEPTS of Section 7.3

RNA Polymerase II Promoters and General Transcription Factors

- RNA polymerase II initiates transcription of genes at the nucleotide in the DNA template that corresponds to the 5' nucleotide that is capped in the encoded mRNA.
- Transcription of protein-coding genes by Pol II can be initiated *in vitro* by sequential binding of the following in the indicated order: TBP, which binds to TATA box DNA; TFIIB; a complex of Pol II and TFIIF; TFIIE; and finally, TFIIH (see Figure 7-17).
- The helicase activity of a TFIIH subunit helps to separate the template strands at the start site in most promoters, a process that requires hydrolysis of ATP. As Pol II begins transcribing away from the start site, its CTD is phosphorylated on serine 5 of the heptapeptide CTD by another TFIIH subunit.
- *In vivo* transcription initiation by Pol II also requires TFIIA and, in metazoans, a complete TFIID protein complex, including its multiple TAF subunits as well as the TBP subunit.

- In metazoans, NELF associates with Pol II after initiation, inhibiting elongation ≈ 50 –200 base pairs from the transcription start site. Inhibition of elongation is relieved when the heterodimeric elongation factors DSIF and CDK9-cyclin T (P-TEFb) associate with the elongation complex and CDK9 phosphorylates subunits of NELF, DSIF, and serine 2 of the Pol II CTD heptapeptide repeat.

7.4 Regulatory Sequences in Protein-Coding Genes and the Proteins Through Which They Function

As noted in the previous section, expression of eukaryotic protein-coding genes is regulated by multiple protein-binding DNA sequences, generically referred to as transcription-control regions. These include promoters and other types of control elements located near transcription start sites, as well as sequences located far from the genes they regulate. In this section, we take a closer look at the properties of various control elements found in eukaryotic protein-coding genes and the proteins that bind to them.

Promoter-Proximal Elements Help Regulate Eukaryotic Genes

Recombinant DNA techniques have been used to systematically mutate the nucleotide sequences of various eukaryotic genes in order to identify transcription-control regions. For example, *linker scanning mutations* can pinpoint the sequences within a regulatory region that function to control transcription. In this approach, a set of constructs with contiguous overlapping mutations are assayed for their effect on expression of a reporter gene or production of a specific mRNA (Figure 7-21a). This type of analysis identified **promoter-proximal elements** of the thymidine kinase (*tk*) gene from herpes simplex type I virus (HSV-I). The results demonstrated that the DNA region upstream of the HSV *tk* gene contains three separate transcription-control sequences: a TATA box in the interval from -32 to -16 and two other control elements farther upstream (Figure 7-21b). Experiments using mutants containing single-base-pair changes in promoter-proximal control elements revealed that they are generally ≈ 6 –10 base pairs long. Recent results indicate that they are found both upstream and downstream of the transcription start site for human genes at equal frequency. While, strictly speaking, the term *promoter* refers to the DNA sequence that determines where a polymerase initiates transcription, the term is often used to refer to both a promoter and its associated promoter-proximal control elements.

To test the spacing constraints on control elements in the HSV *tk* promoter region identified by analysis of linker scanning mutations, researchers prepared and assayed constructs containing small deletions and insertions between

EXPERIMENTAL FIGURE 7-21 Linker scanning mutations identify transcription-control elements. (a) A region of eukaryotic DNA (tan) that supports high-level expression of a reporter gene (light purple) is cloned in a plasmid vector as diagrammed at the top. Overlapping linker scanning (LS) mutations (crosshatch) are introduced from one end of the region being analyzed to the other. These mutations result from scrambling the nucleotide sequence in a short stretch of the DNA. After the mutant plasmids are transfected separately into cultured cells, the activity of the reporter-gene product

is assayed. In the example shown here, the sequence from -120 to +1 of the herpes simplex virus thymidine kinase gene, LS mutations 1, 4, 6, 7, and 9 have little or no effect on expression of the reporter gene, indicating that the regions altered in these mutants contain no control elements. Reporter-gene expression is significantly reduced in mutants 2, 3, 5, and 8, indicating that control elements (brown) lie in the intervals shown at the bottom. (b) Analysis of these LS mutations identified a TATA box and two promoter-proximal elements (PE-1 and PE-2). (Part (b), see S. L. McKnight and R. Kingsbury, 1982, *Science* **217**:316.)

the elements. Changes in spacing between the promoter and promoter-proximal control elements of 20 nucleotides or fewer had little effect. However, insertions of 30 to 50 base pairs between the HSV-1 *tk* promoter-proximal elements and the TATA box was equivalent to deleting the element. Similar analyses of other eukaryotic promoters have also indicated that considerable flexibility in the spacing between promoter-proximal elements is generally tolerated, but separations of several tens of base pairs may decrease transcription.

Distant Enhancers Often Stimulate Transcription by RNA Polymerase II

As noted earlier, transcription from many eukaryotic promoters can be stimulated by control elements located thousands of base pairs away from the start site. Such long-distance transcription-control elements, referred to as enhancers, are

common in eukaryotic genomes but fairly rare in bacterial genomes. Procedures such as linker scanning mutagenesis have indicated that enhancers, usually on the order of ≈ 200 base pairs, like promoter-proximal elements, are composed of several functional sequence elements of ≈ 6 –10 base pairs. As discussed later, each of these regulatory elements is a binding site for a sequence-specific DNA-binding transcription factor.

Analyses of many different eukaryotic cellular enhancers have shown that in metazoans, they can occur with equal probability upstream from a promoter or downstream from a promoter within an intron, or even downstream from the final exon of a gene, as in the case of the *Sal1* gene (see Figure 7-8a). Many enhancers are cell-type specific. For example, an enhancer controlling *Pax6* expression in the retina was characterized in the intron between exons 4 and 5 (see Figure 7-7a), whereas an enhancer controlling *Pax6* expression in the hormone-secreting cells of the pancreas is located

FIGURE 7-22 General organization of control elements that regulate gene expression in multicellular eukaryotes and yeast.

(a) Mammalian genes with a TATA-box promoter are regulated by promoter-proximal elements and enhancers. Promoter elements shown in Figure 7-14 position RNA polymerase II to initiate transcription at the start site and influence the rate of transcription. Enhancers may be either upstream or downstream and as far away as hundreds of kilobases from the transcription start site. In some cases, enhancers lie within introns. Promoter-proximal elements are found upstream and downstream of transcription start sites at equal frequency in mamma-

lian genes. (b) Mammalian CpG-island promoters. Transcription initiates at several sites in both the sense and antisense directions from the ends of the CpG-rich region. Transcripts in the sense direction are elongated and processed into mRNAs by RNA splicing. They express mRNAs with alternative 5' exons determined by the transcription start site. CpG-island promoters contain promoter-proximal control elements. Currently, it is not clear whether they are also regulated by distant enhancers. (c) Most *S. cerevisiae* genes contain only one regulatory region, called an *upstream activating sequence (UAS)*, and a TATA box, which is ≈ 90 base pairs upstream from the start site.

in an ≈ 200 -base-pair region upstream of exon 0 (so named because it was discovered after the exon called "exon 1"). In the important model organism *Saccharomyces cerevisiae* (budding yeast), genes are closely spaced (Figure 6-4b) and few genes contain introns. In this organism, enhancers usually lie within ≈ 200 base pairs upstream of the promoters of the genes they regulate and are referred to by the term *upstream activating sequence (UAS)*.

Most Eukaryotic Genes Are Regulated by Multiple Transcription-Control Elements

Initially, enhancers and promoter-proximal elements were thought to be distinct types of transcription-control elements. However, as more enhancers and promoter-proximal elements were analyzed, the distinctions between them became less clear. For example, both types of element generally can stimulate transcription even when inverted, and both types often are cell-type specific. The general consensus now is that a spectrum of control elements regulates transcription by RNA polymerase II. At one extreme are enhancers, which can stimulate transcription from a promoter tens of thousands of base pairs away. At the other extreme are promoter-proximal elements, such as the upstream elements controlling the HSV *tk* gene, which lose their influence when moved an additional 30–50 base pairs farther from the promoter. Researchers have identified a large number of transcription-

control elements that can stimulate transcription from distances between these two extremes.

Figure 7-22a summarizes the locations of transcription-control sequences for a hypothetical mammalian gene with a promoter containing a TATA box. The start site at which transcription initiates encodes the first (5') nucleotide of the first exon of an mRNA, the nucleotide that is capped. In addition to the TATA box at ≈ -31 to -26 , promoter-proximal elements, which are relatively short (≈ 6 – 10 base pairs), are located within the first ≈ 200 base pairs either upstream or downstream of the start site. Enhancers, in contrast, usually are about 50–200 base pairs long and are composed of multiple elements of ≈ 6 – 10 base pairs. Enhancers may be located up to 50 kilobases or more upstream or downstream from the start site or within an intron. As for the *Pax6* gene, many mammalian genes are controlled by more than one enhancer region that function in different types of cells.

Figure 7-22b summarizes the promoter region of a mammalian gene with a CpG island promoter. About 60–70 percent of mammalian genes are expressed from CpG island promoters, usually at much lower levels than genes with TATA box promoters. Multiple alternative transcription start sites are used, generating mRNAs with alternative 5' ends for the first exon derived from each start site. Transcription occurs in both directions, but Pol II molecules transcribing in the sense direction are elongated to >1 kb much more efficiently than transcripts in the antisense direction.

The *S. cerevisiae* genome contains regulatory elements called **upstream activating sequences (UASs)**, which function similarly to enhancers and promoter-proximal elements in higher eukaryotes. Most yeast genes contain only one UAS, which generally lies within a few hundred base pairs of the start site. In addition, *S. cerevisiae* genes contain a TATA box ≈ 90 base pairs upstream from the transcription start site (Figure 7-22c).

Footprinting and Gel-Shift Assays Detect Protein-DNA Interactions

The various transcription-control elements found in eukaryotic DNA are binding sites for regulatory proteins generally called **transcription factors**. The simplest eukaryotic cells encode hundreds of transcription factors, and the human genome encodes over 2000. The transcription of each gene in the genome is independently regulated by combinations of *specific transcription factors* that bind to its transcription-control regions. The number of possible combinations of this many transcription factors is astronomical, sufficient to generate unique controls for every gene encoded in the genome.

In yeast, *Drosophila*, and other genetically tractable eukaryotes, numerous genes encoding transcriptional activators and repressors have been identified by classical genetic analyses like those described in Chapter 5. However, in mammals and other vertebrates, which are less amenable to such genetic analysis, most transcription factors have been detected initially and subsequently purified by biochemical techniques. In this approach, a DNA regulatory element that has been identified by the kinds of mutational analyses described above is used to identify *cognate* proteins that bind specifically to it. Two common techniques for detecting such cognate proteins are DNase I footprinting and the electrophoretic mobility shift assay.

DNase I footprinting takes advantage of the fact that when a protein is bound to a region of DNA, it protects that DNA sequence from digestion by nucleases. As illustrated in Figure 7-23a, samples of a DNA fragment that is labeled at one end are digested under carefully controlled conditions in the presence and absence of a DNA-binding protein, and then denatured, electrophoresed, and the resulting gel subjected to autoradiography. The region protected by the bound protein appears as a gap, or “footprint,” in the array of bands resulting from digestion in the absence of protein. When footprinting is performed with a DNA fragment containing a known DNA control element, the appearance of a footprint indicates the presence of a transcription factor that binds that control element in the protein sample being assayed. Footprinting also identifies the specific DNA sequence to which the transcription factor binds.

For example, DNase I footprinting of the strong adenovirus late promoter shows a protected region over the TATA box when TBP is added to the labeled DNA before DNase I digestion (Figure 7-23b). DNase I does not digest all phosphodiester bonds in a duplex DNA at equal rate. Consequently, in the absence of added protein (lanes 1, 6, and 9), a particular

pattern of bands is observed that depends on the DNA sequence and results from cleavage at some phosphodiester bonds and not others. However, when increasing amounts of TBP are incubated with the end-labeled DNA before digestion with DNase I, TBP binds to the TATA box and protects the region from ≈ -35 to -20 from digestion when sufficient TBP is added to bind all the labeled DNA molecules. In contrast, increasing amounts of TFIID (lanes 7 and 8) protect both the TATA box region from DNase I digestion, as well as regions near -7 , $+1$ to $+5$, $+10$ to $+15$, and $+20$, producing a different “footprint” from TBP. Results such as this tell us that other subunits of TFIID (the TBP-associated factors or TAFs) also bind to the DNA in the region downstream from the TATA box.

The *electrophoretic mobility shift assay (EMSA)*, also called the *gel-shift* or *band-shift assay*, is more useful than the footprinting assay for quantitative analysis of DNA-binding proteins. In general, the electrophoretic mobility of a DNA fragment is reduced when it is complexed to protein, causing a shift in the location of the fragment band. This assay can be used to detect a transcription factor in protein fractions incubated with a radiolabeled DNA fragment containing a known control element (Figure 7-24). The more of the transcription factor that is added to the binding reaction, the more labeled probe is shifted to the position of the DNA-protein complex.

In the biochemical isolation of a transcription factor, an extract of cell nuclei commonly is subjected sequentially to several types of column chromatography (Chapter 3). Fractions eluted from the columns are assayed by DNase I footprinting or EMSA using DNA fragments containing an identified regulatory element (see Figure 7-21). Fractions containing a protein that binds to the regulatory element in these assays probably contain a putative transcription factor. A powerful technique that is commonly used for the final step in purifying transcription factors is *sequence-specific DNA affinity chromatography*, a particular type of affinity chromatography in which long DNA strands containing multiple copies of the transcription factor-binding site are coupled to a column matrix.

Once a transcription factor is isolated and purified, its partial amino acid sequence can be determined and used to clone the gene or cDNA encoding it, as outlined in Chapter 5. The isolated gene can then be used to test the ability of the encoded protein to activate or repress transcription in an *in vivo* transfection assay (Figure 7-25).

Activators Promote Transcription and Are Composed of Distinct Functional Domains

Studies with a yeast transcription activator called GAL4 provided early insight into the domain structure of transcription factors. The gene encoding the GAL4 protein, which promotes expression of enzymes needed to metabolize galactose, was identified by complementation analysis of *gal4* mutants that cannot form colonies on an agar medium in which galactose is the only source of carbon and energy (Chapter 5). Directed mutagenesis studies like those described previously

EXPERIMENTAL FIGURE 7-23 DNase I footprinting reveals the region of a DNA sequence where a transcription factor binds. (a) A DNA fragment known to contain a control element is labeled at one end with ^{32}P (red dot). Portions of the labeled DNA sample then are digested with DNase I in the presence and absence of protein samples containing a sequence-specific DNA-binding protein. DNase I hydrolyzes the phosphodiester bonds of DNA between the 3' oxygen on the deoxyribose of one nucleotide and the 5' phosphate of the next nucleotide. A low concentration of DNase I is used so that, on average, each DNA molecule is cleaved just once (vertical arrows). If the protein sample does not contain a cognate DNA-binding protein, the DNA fragment is cleaved at multiple positions between the labeled and unlabeled ends of the original fragment, as in sample A (left). If the protein sample contains a protein that binds to a specific sequence in

the labeled DNA, as in sample B (right), the protein binds to the DNA, thereby protecting a portion of the fragment from digestion. Following DNase treatment, the DNA is separated from protein, denatured to separate the strands, and electrophoresed. Autoradiography of the resulting gel detects only labeled strands and reveals fragments extending from the labeled end to the site of cleavage by DNase I. Cleavage fragments containing the control sequence show up on the gel for sample A but are missing in sample B because the bound cognate protein blocked cleavages within that sequence and thus production of the corresponding fragments. The missing bands on the gel constitute the footprint. (b) Footprints produced by increasing amounts of TBP (indicated by the triangle) and of TFIIID on the strong adenovirus major late promoter. [Part (b) from Q. Zhou et al., 1992, *Genes Dev.* 6:1964.]

EXPERIMENTAL FIGURE 7-24 Electrophoretic mobility shift assay can be used to detect transcription factors during purification. In this example, protein fractions separated by column chromatography were assayed for their ability to bind to a radiolabeled DNA-fragment probe containing a known regulatory element. After an aliquot of the protein sample was loaded onto the column (ON) and successive column fractions (numbers) were incubated with the labeled probe, the samples were electrophoresed under conditions that do not disrupt protein-DNA interactions. The free probe not bound to protein migrated to the bottom of the gel. A protein in the preparation applied to the column and in fractions 7 and 8 bound to the probe, forming a DNA-protein complex that migrated more slowly than the free probe. These fractions therefore likely contain the regulatory protein being sought. [From S. Yoshinaga et al., 1989, *J. Biol. Chem.* 264:10529.]

EXPERIMENTAL FIGURE 7-25 In vivo transfection assay measures transcription activity to evaluate proteins believed to be transcription factors. The assay system requires two plasmids. One plasmid contains the gene encoding the putative transcription factor (protein X). The second plasmid contains a reporter gene (e.g., luciferase) and one or more binding sites for protein X. Both plasmids are simultaneously introduced into cells that lack the gene encoding protein X. The production of reporter-gene RNA transcripts is measured; alternatively, the activity of the encoded protein can be assayed. If reporter-gene transcription is greater in the presence of the X-encoding plasmid than in its absence, then the protein is an activator; if transcription is less, then it is a repressor. By use of plasmids encoding a mutated or rearranged transcription factor, important domains of the protein can be identified.

identified UASs for the genes activated by GAL4. Each of these UASs was found to contain one or more copies of a related 17-bp sequence called UAS_{GAL}. DNase I footprinting assays with recombinant GAL4 protein produced in *E. coli* from the yeast GAL4 gene showed that GAL4 protein binds to UAS_{GAL} sequences. When a copy of UAS_{GAL} was cloned upstream of a TATA box followed by a β -galactosidase reporter gene, expression of β -galactosidase was activated in galactose media in wild-type cells but not in *gal4* mutants. These results showed that UAS_{GAL} is a transcription-control element activated by the GAL4 protein in galactose media.

A remarkable set of experiments with *gal4* deletion mutants demonstrated that the GAL4 transcription factor is composed of separable functional domains: an N-terminal DNA-binding domain, which binds to specific DNA sequences, and a C-terminal activation domain, which interacts with other proteins to stimulate transcription from a nearby promoter (Figure 7-26). When the N-terminal DNA-binding domain of GAL4 was fused directly to various portions of its own C-terminal region, the resulting truncated proteins retained the ability to stimulate expression of a reporter gene in

an in vivo assay like that depicted in Figure 7-25. Thus the internal portion of the protein is not required for functioning of GAL4 as a transcription factor. Similar experiments with another yeast transcription factor, GCN4, which regulates genes required for synthesis of many amino acids, indicated that it contains an ≈ 50 -amino acid DNA-binding domain at its C-terminus and an ≈ 20 -amino acid activation domain near the middle of its sequence.

Further evidence for the existence of distinct activation domains in GAL4 and GCN4 came from experiments in which their activation domains were fused to a DNA-binding domain from an entirely unrelated *E. coli* DNA-binding protein. When these fusion proteins were assayed in vivo, they activated transcription of a reporter gene containing the cognate site for the *E. coli* protein. Thus functional transcription factors can be constructed from entirely novel combinations of prokaryotic and eukaryotic elements.

Studies such as these have now been carried out with many eukaryotic activators. The structural model of eukaryotic activators that has emerged from these studies is a modular one in which one or more activation domains are connected to a sequence-specific DNA-binding domain through flexible protein domains (Figure 7-27). In some cases, amino acids included in the DNA-binding domain also contribute to transcriptional activation. As discussed in a later section, activation domains are thought to function by binding other proteins involved in transcription. The presence of flexible domains connecting the DNA-binding domains to activation domains may explain why alterations in the spacing between control elements are so well tolerated in eukaryotic control regions. Thus even when the positions of transcription factors bound to DNA are shifted relative to each other, their activation domains may still be able to interact because they are attached to their DNA-binding domains through flexible protein regions.

Repressors Inhibit Transcription and Are the Functional Converse of Activators

Eukaryotic transcription is regulated by repressors as well as activators. For example, geneticists have identified mutations in yeast that result in continuously high expression of certain genes. This type of unregulated, abnormally high expression is called **constitutive** expression and results from the inactivation of a repressor that normally inhibits the transcription of these genes. Similarly, mutants of *Drosophila* and *Caenorhabditis elegans* have been isolated that are defective in embryonic development because they express genes in embryonic cells where those genes are normally repressed. The mutations in these mutants inactivate repressors, leading to abnormal development.

Repressor-binding sites in DNA have been identified by systematic linker scanning mutation analysis similar to that depicted in Figure 7-21. In this type of analysis, mutation of an activator-binding site leads to decreased expression of the linked reporter gene, whereas mutation of a repressor-binding site leads to increased expression of a reporter gene. Repressor proteins that bind such sites can be purified and

EXPERIMENTAL FIGURE 7-26 Deletion mutants of the *GAL4* gene in yeast with a *UAS_{GAL}* reporter-gene construct demonstrate the separate functional domains in an activator.

(a) Diagram of DNA construct containing a *lacZ* reporter gene (encoding β -galactosidase) and TATA box ligated to *UAS_{GAL}*, a regulatory element that contains several *GAL4*-binding sites. The reporter-gene construct and DNA encoding wild-type or mutant (deleted) *GAL4* were simultaneously introduced into mutant (*gal4*) yeast cells, and the activity of β -galactosidase expressed from *lacZ* was assayed.

Activity will be high if the introduced *GAL4* DNA encodes a functional protein. (b) Schematic diagrams of wild-type *GAL4* and various mutant forms. Small numbers refer to positions in the wild-type sequence. Deletion of 50 amino acids from the N-terminal end destroyed the ability of *GAL4* to bind to *UAS_{GAL}* and to stimulate expression of β -galactosidase from the reporter gene. Proteins with extensive deletions from the C-terminal end still bound to *UAS_{GAL}*. These results localize the DNA-binding domain to the N-terminal end of *GAL4*. The ability to activate β -galactosidase expression was not entirely eliminated unless somewhere between 126 and 189 or more amino acids were deleted from the C-terminal end. Thus the activation domain lies in the C-terminal region of *GAL4*. Proteins with internal deletions (bottom) also were able to stimulate expression of β -galactosidase, indicating that the central region of *GAL4* is not crucial for its function in this assay. [See J. Ma and M. Ptashne, 1987, *Cell* 48:847; I. A. Hope and K. Struhl, 1986, *Cell* 46:885; and R. Brent and M. Ptashne, 1985, *Cell* 43:729.]

FIGURE 7-27 Schematic diagrams illustrating the modular structure of eukaryotic transcription activators. Transcription factors may contain more than one activation domain but rarely contain more than one DNA-binding domain. *GAL4* and *GCN4* are yeast transcription activators. The glucocorticoid receptor (*GR*) promotes transcription of target genes when certain hormones are bound to the C-terminal activation domain. *SP1* binds to GC-rich promoter elements in a large number of mammalian genes.

assayed using the same biochemical techniques described earlier for activator proteins.

Eukaryotic transcription repressors are the functional converse of activators. They can inhibit transcription from a gene they do not normally regulate when their cognate binding sites are placed within tens of base pairs to many kilobases of the gene's start site. Like activators, most eukaryotic repressors are modular proteins that have two functional domains: a DNA-binding domain and a repression domain. Similar to activation domains, repression domains continue to function when fused to another type of DNA-binding domain. If binding sites for this second DNA-binding domain are inserted within a few hundred base pairs of a promoter, expression of the fusion protein inhibits transcription from the promoter. Also like activation domains, repression domains function by interacting with other proteins, as discussed later in this chapter.

DNA-Binding Domains Can Be Classified into Numerous Structural Types

The DNA-binding domains of eukaryotic activators and repressors contain a variety of structural motifs that bind specific DNA sequences. The ability of DNA-binding proteins to bind to specific DNA sequences commonly results from noncovalent interactions between atoms in an α helix in the

FIGURE 7-28 Interaction of bacteriophage 434 repressor with DNA. (a) Ribbon diagram of 434 repressor bound to its specific operator DNA. Repressor monomers are in yellow and green. The recognition helices are indicated by asterisks. A space-filling model of the repressor-operator complex (b) shows how the protein interacts intimately with one side of the DNA molecule over a length of 1.5 turns. [Adapted from A. K. Aggarwal et al., 1988, *Science* **242**:699.]

DNA-binding domain and atoms on the edges of the bases within a major groove in the DNA. Ionic interactions between positively charged residues arginine and lysine and negatively charged phosphates in the sugar phosphate backbone and, in some cases, interactions with atoms in a DNA minor groove also contribute to binding.

The principles of specific protein-DNA interactions were first discovered during the study of bacterial repressors. Many bacterial repressors are dimeric proteins in which an α helix from each monomer inserts into a major groove in the DNA helix (Figure 7-28). This α helix is referred to as the *recognition helix* or *sequence-reading helix*, because most of the amino acid side chains that contact DNA extend from this helix. The recognition helix that protrudes from the surface of bacterial repressors to enter the DNA major groove and make multiple, specific interactions with atoms in the DNA is usually supported in the protein structure in part by hydrophobic interactions with a second α helix just N-terminal to it. This structural element, which is present in many bacterial repressors, is called a *helix-turn-helix* motif.

Many additional motifs that can present an α helix to the major groove of DNA are found in eukaryotic transcription factors, which often are classified according to the type of DNA-binding domain they contain. Because most of these motifs have characteristic consensus amino acid sequences, potential transcription factors can be recognized among the cDNA sequences from various tissues that have been characterized in humans and other species. The human genome, for instance, encodes ≈ 2000 transcription factors.

Here we introduce several common classes of DNA-binding proteins whose three-dimensional structures have been determined. In all these examples and many other transcription factors, at least one α helix is inserted into a major groove of DNA. However, some transcription factors contain alternative structural motifs (e.g., β strands and loops, see NFAT in Figure 7-32 as an example) that interact with DNA.

Homeodomain Proteins Many eukaryotic transcription factors that function during development contain a conserved 60-residue DNA-binding motif, called a **homeodomain**, that is similar to the helix-turn-helix motif of bacterial repressors. These transcription factors were first identified in *Drosophila* mutants in which one body part was transformed into another during development (see Figure 7-1b). The conserved homeodomain sequence has also been found in vertebrate transcription factors, including those that have similar master-control functions in human development.

Zinc-Finger Proteins A number of different eukaryotic proteins have regions that fold around a central Zn^{2+} ion, producing a compact domain from a relatively short length of the polypeptide chain. Termed a **zinc finger**, this structural motif was first recognized in DNA-binding domains but now is known to occur also in proteins that do not bind to DNA. Here we describe two of the several classes of zinc-finger motifs that have been identified in eukaryotic transcription factors.

The C_2H_2 *zinc finger* is the most common DNA-binding motif encoded in the human genome and the genomes of most other multicellular animals. It is also common in multicellular plants but is not the dominant type of DNA-binding domain in plants as it is in animals. This motif has a 23- to 26-residue consensus sequence containing two conserved cysteine (C) and two conserved histidine (H) residues, whose side chains bind one Zn^{2+} ion (Figure 3-9c). The name “zinc finger” was coined because a two-dimensional diagram of the structure resembles a finger. When the three-dimensional structure was solved, it became clear that the binding of the Zn^{2+} ion by the two cysteine and two histidine residues folds the relatively short polypeptide sequence into a compact domain, which can insert its α helix into the major groove of DNA. Many transcription factors contain multiple C_2H_2 zinc fingers, which interact with successive groups of base pairs, within the major groove, as the protein wraps around the DNA double helix (Figure 7-29a).

A second type of zinc-finger structure, designated the C_4 *zinc finger* (because it has four conserved cysteines in contact with the Zn^{2+}), is found in ≈ 50 human transcription factors. The first members of this class were identified as specific intracellular high-affinity binding proteins, or “receptors,” for steroid hormones, leading to the name *steroid receptor superfamily*. Because similar intracellular receptors for nonsteroid hormones subsequently were found, these transcription factors are now commonly called **nuclear receptors**. The characteristic feature of C_4 zinc fingers is the presence of two groups of four critical cysteines, one toward each end of the 55- or 56-residue domain. Although the C_4 zinc finger initially was named by analogy with the C_2H_2 zinc finger, the

FIGURE 7-29 Eukaryotic DNA-binding domains that use an α helix to interact with the major groove of specific DNA sequences.

(a) The GL1 DNA-binding domain is monomeric and contains five C_2H_2 zinc fingers. The α helices are shown as cylinders, the Zn^{2+} ions as spheres. Finger 1 does not interact with DNA, whereas the other four fingers do. (b) The glucocorticoid receptor is a homodimeric C_4 zinc-finger protein. The α helices are shown as purple ribbons, the β -strands as green arrows, the Zn^{2+} ions as spheres. Two α helices (darker shade), one in each monomer, interact with the DNA. Like all C_4 zinc-finger homodimers, this transcription factor has twofold rotational symmetry; the center of symmetry is shown by the yellow ellipse. (c) In

leucine-zipper proteins, basic residues in the extended α -helical regions of the monomers interact with the DNA backbone at adjacent major grooves. The coiled-coil dimerization domain is stabilized by hydrophobic interactions between the monomers. (d) In bHLH proteins, the DNA-binding helices at the bottom (N-termini of the monomers) are separated by nonhelical loops from a leucine-zipper-like region containing a coiled-coil dimerization domain. [Part (a), see N. P. Pavletich and C. O. Pabo, 1993, *Science* **261**:1701. Part (b), see B. F. Luisi et al., 1991, *Nature* **352**:497. Part (c), see T. E. Ellenberger et al., 1992, *Cell* **71**:1223. Part (d), see A. R. Ferre-D'Amare et al., 1993, *Nature* **363**:38.]

three-dimensional structures of proteins containing these DNA-binding motifs later were found to be quite distinct. A particularly important difference between the two is that C_2H_2 zinc-finger proteins generally contain three or more repeating finger units and bind as monomers, whereas C_4 zinc-finger proteins generally contain only two finger units and generally bind to DNA as homodimers or heterodimers. Homodimers of C_4 zinc-finger DNA-binding domains have twofold rotational symmetry (Figure 7-29b). Consequently, homodimeric nuclear receptors bind to consensus DNA sequences that are inverted repeats.

Leucine-Zipper Proteins Another structural motif present in the DNA-binding domains of a large class of transcription factors contains the hydrophobic amino acid leucine at every seventh position in the sequence. These proteins bind to DNA as dimers, and mutagenesis of the leucines showed that they were required for dimerization. Consequently, the name **leucine zipper** was coined to denote this structural motif.

The DNA-binding domain of the yeast GCN4 transcription factor mentioned earlier is a leucine-zipper domain. X-ray crystallographic analysis of complexes between DNA and the GCN4 DNA-binding domain has shown that the dimeric protein contains two extended α helices that “grip” the DNA molecule, much like a pair of scissors, at two adjacent major grooves separated by about half a turn of the double helix (Figure 7-29c). The portions of the α helices contacting the DNA include positively charged (basic) residues that interact with phosphates in the DNA backbone and additional residues that interact with specific bases in the major groove.

GCN4 forms dimers via hydrophobic interactions between the C-terminal regions of the α helices, forming a coiled-coil structure. This structure is common in proteins containing amphipathic α helices in which hydrophobic amino acid residues are regularly spaced alternately three or four positions apart in the sequence, forming a stripe down one side of the α helix. These hydrophobic stripes make up the interacting surfaces between the α -helical monomers in a coiled-coil dimer (see Figure 3-9a).

Although the first leucine-zipper transcription factors to be analyzed contained leucine residues at every seventh position in the dimerization region, additional DNA-binding proteins containing other hydrophobic amino acids in these positions subsequently were identified. Like leucine-zipper proteins, they form dimers containing a C-terminal coiled-coil dimerization region and an N-terminal DNA-binding domain. The term *basic zipper* (*bZIP*) now is frequently used to refer to all proteins with these common structural features. Many basic-zipper transcription factors are heterodimers of two different polypeptide chains, each containing one basic-zipper domain.

Basic Helix-Loop-Helix (bHLH) Proteins The DNA-binding domain of another class of dimeric transcription factors contains a structural motif very similar to the basic-zipper motif except that a nonhelical loop of the polypeptide chain separates two α -helical regions in each monomer (Figure 7-29d).

Termed a **basic helix-loop-helix (bHLH)**, this motif was predicted from the amino acid sequences of these proteins, which contain an N-terminal α helix with basic residues that interact with DNA, a middle loop region, and a C-terminal region with hydrophobic amino acids spaced at intervals characteristic of an amphipathic α helix. As with basic-zipper proteins, different bHLH proteins can form heterodimers.

Structurally Diverse Activation and Repression Domains Regulate Transcription

Experiments with fusion proteins composed of the GAL4 DNA-binding domain and random segments of *E. coli* proteins demonstrated that a diverse group of amino acid sequences can function as activation domains, ≈ 1 percent of all *E. coli* sequences, even though they evolved to perform other functions. Many transcription factors contain activation domains marked by an unusually high percentage of particular amino acids. GAL4, GCN4, and most other yeast transcription factors, for instance, have activation domains that are rich in acidic amino acids (aspartic and glutamic acids). These so-called *acidic activation domains* generally are capable of stimulating transcription in nearly all types of eukaryotic cells—fungal, animal, and plant cells. Activation domains from some *Drosophila* and mammalian transcription factors are glutamine-rich, and some are proline-rich; still others are rich in the closely related amino acids serine and threonine, both of which have hydroxyl groups. However, some strong activation domains are not particularly rich in any specific amino acid.

Biophysical studies indicate that acidic activation domains have an unstructured, random-coil conformation. These domains stimulate transcription when they are bound to a protein *co-activator*. The interaction with a co-activator causes the activation domain to assume a more structured α -helical conformation in the activation domain–co-activator complex. A well-studied example of a transcription factor with an acidic activation domain is the mammalian CREB protein, which is phosphorylated in response to increased levels of cAMP. This regulated phosphorylation is required for CREB to bind to its co-activator CBP (CREB binding protein), resulting in the transcription of genes whose control regions contain a CREB-binding site (see Figure 15-32). When the phosphorylated random coil activation domain of CREB interacts with CBP, it undergoes a conformational change to form two α helices linked by a short loop, which wrap around the interacting domain of CBP (Figure 7-30a).

Some activation domains are larger and more highly structured than acidic activation domains. For example, the ligand-binding domains of nuclear receptors function as activation domains when they bind their specific ligand (Figure 7-30b, c). Binding of ligand induces a large conformational change that allows the ligand-binding domain with bound hormone to interact with a short α helix in nuclear-receptor co-activators; the resulting complex then can activate transcription of genes whose control regions bind the nuclear receptor.

FIGURE 7-30 Activation domains may be random coils until they interact with co-activator proteins or folded protein domains.

(a) The activation domain of CREB (cyclic AMP response element-binding protein) is activated by phosphorylation at serine 123. It is a random coil until it interacts with a domain of the CBP co-activator (shown as a space-filling surface model with negatively charged regions in red and positively charged regions in blue). When the CREB activation domain binds to CBP, it folds into two amphipathic α helices. Side chains in the activation domain that interact with the surface of the CBP domain are shown. (b) The ligand-binding activation domain of the estrogen receptor is a folded-protein domain. When estrogen is bound to the domain, the green α helix interacts with the ligand, generating a hydrophobic groove in the ligand-binding domain (dark brown helices), which binds an amphipathic α helix in a co-activator subunit (blue). (c) The conformation of the estrogen receptor in the absence of hormone is stabilized by binding of the estrogen antagonist tamoxifen. In this conformation, the green helix of the receptor folds into a conformation that interacts with the co-activator-binding groove of the active receptor, sterically blocking binding of co-activators. [Part (a) from I. Radhakrishnan et al. (1997) *Cell* **91**:741, courtesy of Peter Wright. Parts (b) and (c) from A. K. Shiau et al., 1998, *Cell* **95**:927.]

Thus the acidic activation domain in CREB and the ligand-binding activation domains in nuclear receptors represent two structural extremes. The CREB acidic activation domain is a random coil that folds into two α helices when it binds to the surface of a globular domain in a co-activator. In contrast, the

nuclear-receptor ligand-binding activation domain is a structured globular domain that interacts with a short α helix in a co-activator, which probably is a random coil before it is bound. In both cases, however, specific protein-protein interactions between co-activators and the activation domains permit the transcription factors to stimulate gene expression.

Currently, less is known about the structure of repression domains. The globular ligand-binding domains of some nuclear receptors function as repression domains in the absence of their specific hormone ligand. Like activation domains, repression domains may be relatively short, comprising 15 or fewer amino acids. Biochemical and genetic studies indicate that repression domains also mediate protein-protein interactions and bind to *co-repressor* proteins, forming a complex that inhibits transcription initiation by mechanisms that are discussed later in the chapter.

Transcription Factor Interactions Increase Gene-Control Options

Two types of DNA-binding proteins discussed previously—basic-zipper proteins and bHLH proteins—often exist in alternative heterodimeric combinations of monomers. Other classes of transcription factors not discussed here also form heterodimeric proteins. In some heterodimeric transcription factors, each monomer recognizes the same sequence. In these proteins, the formation of alternative heterodimers does not increase the number of different sites on which the monomers can act, but rather allows the activation domains associated with each monomer to be brought together in alternative combinations that bind to the same site (Figure 7-31a). As we will see later, and in subsequent chapters, the activities of individual transcription factors can be regulated by multiple mechanisms. Consequently, a single bZIP or bHLH DNA regulatory element in the control region of a gene may elicit different transcriptional responses depending on which bZIP or bHLH monomers that bind to that site are expressed in a particular cell at a particular time and how their activities are regulated.

In some heterodimeric transcription factors, however, each monomer has a different DNA-binding specificity. The resulting combinatorial possibilities increase the number of potential DNA sequences that a family of transcription factors can bind. Three different factor monomers theoretically could combine to form six homo- and heterodimeric factors, as illustrated in Figure 7-31b. Four different factor monomers could form a total of 10 dimeric factors, five monomers, 16 dimeric factors, and so forth. In addition, inhibitory factors are known that bind to some basic-zipper and bHLH monomers, thereby blocking their binding to DNA. When these inhibitory factors are expressed, they repress transcriptional activation by the factors with which they interact (Figure 7-31c). The rules governing the interactions of members of a heterodimeric transcription factor class are complex. This combinatorial complexity expands both the number of DNA sites from which these factors can activate transcription and the ways in which they can be regulated.

FIGURE 7-31 Combinatorial possibilities due to formation of heterodimeric transcription factors. (a) In some heterodimeric transcription factors, each monomer recognizes the same DNA sequence. In the hypothetical example shown, transcription factors A, B, and C can all interact with one another, creating six different alternative combinations of activation domains that can all bind at the same site. Each composite binding site is divided into two half-sites, and each heterodimeric factor contains the activation domains of its two constituent monomers. (b) When transcription-factor monomers recognize different DNA sequences, alternative combinations of the three factors bind to six different DNA sequences (sites 1–6), each with a unique combination of activation domains. (c) Expression of an inhibitory factor (red) that interacts only with factor A inhibits binding; hence transcriptional activation at sites 1, 4, and 5 is inhibited, but activation at sites 2, 3, and 6 is unaffected.

Similar combinatorial transcriptional regulation is achieved through the interaction of structurally unrelated transcription factors bound to closely spaced binding sites in DNA. An example is the interaction of two transcription factors, NFAT and AP1, which bind to neighboring sites in a composite promoter-proximal element regulating the gene encoding interleukin-2 (IL-2). Expression of the *IL-2* gene is critical to the immune response, but abnormal expression of IL-2 can lead to autoimmune diseases such as rheumatoid arthritis. Neither NFAT nor AP1 binds to its site in the *IL-2* control region in the absence of the other. The affinities of the factors for these particular DNA sequences are too low for the individual factors to form a stable complex with

DNA. However, when both NFAT and AP1 are present, protein-protein interactions between them stabilize the DNA ternary complex composed of NFAT, AP1, and DNA (Figure 7-32a). Such *cooperative DNA binding* of various transcription factors results in considerable combinatorial complexity of transcription control. As a result, the ≈ 2000 transcription factors encoded in the human genome can bind to DNA through a much larger number of cooperative interactions, resulting in unique transcriptional control for each of

FIGURE 7-32 Cooperative binding of two unrelated transcription factors to neighboring sites in a composite control element. (a) By themselves, both monomeric NFAT and heterodimeric AP1 transcription factors have low affinity for their respective binding sites in the *IL-2* promoter-proximal region. Protein-protein interactions between NFAT and AP1 add to the overall stability of the NFAT-AP1-DNA complex, so that the two proteins bind to the composite site cooperatively. (b) Cooperative DNA binding by dimeric SRF and monomeric SAP-1 can occur when their binding sites are separated by 5 to ≈ 30 bp and when the SAP-1 binding site is inverted because the B-box domain of SAP-1 that interacts with SRF is connected to the ETS DNA-binding domain of SAP-1 by a flexible linker region of the SAP-1 polypeptide chain (dotted line). [a] See L. Chen et al., 1998, *Nature* **392**:42; [b] see M. Hassler and T. J. Richmond, 2001, *EMBO J.* **20**:3018.]

the $\approx 25,000$ human genes. In the case of *IL-2*, transcription occurs only when both NFAT is activated, resulting in its transport from the cytoplasm to the nucleus, and the two subunits of AP1 are synthesized. These events are controlled by distinct signal transduction pathways (Chapters 15 and 16), allowing stringent control of *IL-2* expression.

Cooperative binding by NFAT and AP1 occurs only when their weak binding sites are positioned quite close to each other in DNA. The sites must be located at a precise distance from each other for effective binding. The requirements for cooperative binding are not so stringent in the case of some other transcription factors and control regions. For example, the *EGR-1* control region contains a composite binding site to which the SRF and SAP1 transcription factors bind cooperatively (see Figure 7-32b). Because a SAP1 has a long, flexible domain that interacts with SRF, the two proteins can bind cooperatively when their individual sites in DNA are separated by any distance up to ≈ 30 base pairs or are inverted relative to each other.

Multiprotein Complexes Form on Enhancers

As noted previously, enhancers generally range in length from about 50 to 200 base pairs and include binding sites for several transcription factors. Analysis of the ≈ 50 -bp enhancer that regulates expression of β -interferon, an important protein in defense against viral infections in vertebrates, provides a good example of one of the few examples thus far of the structure of the DNA-binding domains bound to the several transcription factor-binding sites that comprise an enhancer (Figure 7-33). The term **enhanceosome** has been coined to describe such large

DNA-protein complexes that assemble from transcription factors as they bind to their multiple binding sites in an enhancer.

Because of the presence of flexible regions connecting the DNA-binding domains and activation or repression domains in transcription factors (see Figure 7-27), and the ability of interacting proteins bound to distant sites to produce loops in the DNA between their binding sites (Figure 7-4), considerable leeway in the spacing between regulatory elements in transcription-control regions is permissible. This tolerance for variable spacing between binding sites for regulatory transcription factors and promoter-binding sites for the general transcription factors and Pol II probably contributed to rapid evolution of gene control in eukaryotes. Transposition of DNA sequences and recombination between repeated sequences over evolutionary time likely created new combinations of control elements that were subjected to natural selection and retained if they proved beneficial. The latitude in spacing between regulatory elements probably allowed many more functional combinations to be subjected to this evolutionary experimentation than would be the case if constraints on the spacing between regulatory elements were strict, as for most genes in bacteria.

KEY CONCEPTS of Section 7.4

Regulatory Sequences in Protein-Coding Genes and the Proteins Through Which They Function

- Expression of eukaryotic protein-coding genes generally is regulated through multiple protein-binding control regions that are located close to or distant from the transcription start site (Figure 7-22).
- Promoters direct binding of RNA polymerase II to DNA, determine the site of transcription initiation, and influence transcription rate.
- Three principal types of promoter sequences have been identified in eukaryotic DNA. The TATA box is prevalent in highly transcribed genes. Initiator promoters are found in some genes, and CpG islands, the promoters for 60–70 percent of protein-coding genes in vertebrates, are characteristic of genes transcribed at a low rate.
- Promoter-proximal elements occur within ≈ 200 base pairs of a start site. Several such elements, containing ≈ 6 –10 base pairs, may help regulate a particular gene.
- Enhancers, which contain multiple short control elements, may be located from 200 base pairs to tens of kilobases upstream or downstream from a promoter, within an intron, or downstream from the final exon of a gene.
- Promoter-proximal elements and enhancers often are cell-type specific, functioning only in specific differentiated cell types.
- Transcription factors, which stimulate or repress transcription, bind to promoter-proximal regulatory elements and enhancers in eukaryotic DNA.

FIGURE 7-33 Model of the enhanceosome that forms on the β -interferon enhancer. Two heterodimeric factors, Jun/ATF-2 and p50/RelA (NF- κ B), and two copies each of the monomeric transcription factors IRF-3 and IRF-7, bind to the six overlapping binding sites in this enhancer. [Adapted from D. Penne, T. Manniatis, and S. Harrison, 2007, *Cell* 129:1111.]

- Transcription activators and repressors are generally modular proteins containing a single DNA-binding domain and one or a few activation domains (for activators) or repression domains (for repressors). The different domains frequently are linked through flexible polypeptide regions (see Figure 7-27).
- Among the most common structural motifs found in the DNA-binding domains of eukaryotic transcription factors are the C_2H_2 zinc finger, homeodomain, basic helix-loop-helix (bHLH), and basic zipper (leucine zipper). All these and many other DNA-binding motifs contain one or more α helices that interact with major grooves in their cognate site in DNA.
- Activation and repression domains in transcription factors exhibit a variety of amino acid sequences and three-dimensional structures. In general, these functional domains interact with co-activators or co-repressors, which are critical to the ability of transcription factors to modulate gene expression.
- The transcription-control regions of most genes contain binding sites for multiple transcription factors. Transcription of such genes varies depending on the particular repertoire of transcription factors that are expressed and activated in a particular cell at a particular time.
- Combinatorial complexity in transcription control results from alternative combinations of monomers that form heterodimeric transcription factors (see Figure 7-31) and from cooperative binding of transcription factors to composite control sites (see Figure 7-32).
- Binding of multiple activators to nearby sites in an enhancer forms a multiprotein complex called an enhanceosome (see Figure 7-33).

7.5 Molecular Mechanisms of Transcription Repression and Activation

The repressors and activators that bind to specific sites in DNA and regulate expression of the associated protein-coding genes do so by three general mechanisms. First, these regulatory proteins act in concert with other proteins to modulate chromatin structure, inhibiting or stimulating the ability of general transcription factors to bind to promoters. Recall from Chapter 6 that the DNA in eukaryotic cells is not free but is associated with a roughly equal mass of protein in the form of **chromatin**. The basic structural unit of chromatin is the **nucleosome**, which is composed of ≈ 147 base pairs of DNA wrapped tightly around a disk-shaped core of **histone** proteins. Residues within the N-terminal region of each histone, and the C-terminal regions of histones H2A and H2B, called **histone tails**, extend from the surface of the nucleosome and can be reversibly modified (see Figure 6-31b). Such modifications influence the relative condensation of chromatin and thus its accessibility to proteins required for transcription initiation. In addition to their role in such

chromatin-mediated transcriptional control, activators and repressors interact with a large multiprotein complex called the *mediator of transcription complex*, or simply **mediator**. This complex in turn binds to Pol II and directly regulates assembly of transcription preinitiation complexes. In addition, some activation domains interact with TFIID-TAF subunits or other components of the preinitiation complex, interactions that contribute to preinitiation complex assembly. Finally, activation domains may also interact with the elongation factor P-TEFb (CDK9-cyclin T) and other as yet unknown factors to stimulate Pol II elongation away from the promoter region.

In this section, we review the current understanding of how repressors and activators control chromatin structure and preinitiation complex assembly. In the next section of the chapter, we discuss how the concentrations and activities of activators and repressors themselves are controlled, so that gene expression is precisely attuned to the needs of the cell and organism.

Formation of Heterochromatin Silences Gene Expression at Telomeres, Near Centromeres, and in Other Regions

For many years it has been clear that inactive genes in eukaryotic cells are often associated with **heterochromatin**, regions of chromatin that are more highly condensed and stain more darkly with DNA dyes than **euchromatin**, where most transcribed genes are located (see Figure 6-33a). Regions of chromosomes near the centromeres and telomeres and additional specific regions that vary in different cell types are organized into heterochromatin. The DNA in heterochromatin is less accessible to externally added proteins than DNA in euchromatin and consequently is often referred to as “closed” chromatin. For instance, in an experiment described in Chapter 6, the DNA of inactive genes was found to be far more resistant to digestion by DNase I than the DNA of transcribed genes (see Figure 6-32).

Study of DNA regions in *S. cerevisiae* that behave like the heterochromatin of higher eukaryotes provided early insight into the *chromatin-mediated repression* of transcription. This yeast can grow either as haploid or diploid cells. Haploid cells exhibit one of two possible mating types, called **a** and **α** . Cells of different mating type can “mate,” or fuse, to generate a diploid cell. When a haploid cell divides by budding, the larger “mother” cell switches its mating type. Genetic and molecular analyses have revealed that three genetic loci on yeast chromosome III control the mating type of yeast cells (Figure 7-34). Only the central mating-type locus, termed **MAT**, is actively transcribed and expresses transcription factors ($\alpha 1$, or $\alpha 1$ and $\alpha 2$) that regulate genes controlling the mating type. In any one cell, either an **a** or **α** DNA sequence is located at the **MAT**. The two additional loci, termed **HML** and **HMR**, near the left and right telomere, respectively, contain “silent” (nontranscribed) copies of the **a** or **α** genes. These sequences are transferred alternately from **HML α** or **HMR α** into the **MAT locus** by a type of nonreciprocal recombination between sister chromatids during cell division. When the

FIGURE 7-34 Arrangement of mating-type loci on chromosome III in the yeast *S. cerevisiae*. Silent (unexpressed) mating-type genes (either *a* or α , depending on the strain) are located at the *HML* locus. The opposite mating-type gene is present at the silent *HMR* locus. When the α or *a* sequences are present at the *MAT* locus, they can be

transcribed into mRNAs whose encoded proteins specify the mating-type phenotype of the cell. The silencer sequences near *HML* and *HMR* bind proteins that are critical for repression of these silent loci. Haploid cells can switch mating types in a process that transfers the DNA sequence from *HML* or *HMR* to the transcriptionally active *MAT* locus.

MAT locus contains the DNA sequence from *HML* α , the cells behave as α cells. When the *MAT* locus contains the DNA sequence from *HMRa*, the cells behave like *a* cells.

Our interest here is how transcription of the silent mating-type loci at *HML* and *HMR* is repressed. If the genes at these loci are expressed, as they are in yeast mutants with defects in the repressing mechanism, both *a* and α proteins are expressed, causing the cells to behave like diploid cells, which cannot mate. The promoters and UASs controlling transcription of the *a* and α genes lie near the center of the DNA sequence that is transferred and are identical whether the sequences are at the *MAT* locus or at one of the silent loci. This indicates that the function of the transcription factors that interact with these sequences must somehow be blocked at *HML* and *HMR* but not at the *MAT* locus. This repression of the silent loci depends on **silencer sequences** located next to the region of transferred DNA at *HML* and *HMR* (Figure 7-34). If the silencer is deleted, the adjacent locus is transcribed. Remarkably, any gene placed near the yeast mating-type silencer sequence by recombinant DNA techniques is repressed, or “silenced,” even a tRNA gene transcribed by RNA polymerase III, which uses a different set of general transcription factors than RNA polymerase II uses, as discussed later.

Several lines of evidence indicate that repression of the *HML* and *HMR* loci results from a condensed chromatin structure that sterically blocks transcription factors from interacting with the DNA. In one telling experiment, the gene encoding an *E. coli* enzyme that methylates adenine residues in GATC sequences was introduced into yeast cells under the control of a yeast promoter so that the enzyme was expressed. Researchers found that GATC sequences within the *MAT* locus and most other regions of the genome in these cells were methylated, but not those within the *HML* and *HMR* loci. These results indicate that the DNA of the silent loci is inaccessible to the *E. coli* methylase and presumably to proteins in general, including transcription factors and RNA

polymerase. Similar experiments conducted with various yeast histone mutants indicated that specific interactions involving the histone tails of H3 and H4 are required for formation of a fully repressed chromatin structure. Other studies have shown that the telomeres of every yeast chromosome also behave like silencer sequences. For instance, when a gene is placed within a few kilobases of any yeast telomere, its expression is repressed. In addition, this repression is relieved by the same mutations in the H3 and H4 histone tails that interfere with repression at the silent mating-type loci.

Genetic studies led to identification of several proteins, RAP1 and three SIR proteins, that are required for repression of the silent mating-type loci and the telomeres in yeast. RAP1 was found to bind within the DNA silencer sequences associated with *HML* and *HMR* and to a sequence that is repeated multiple times at each yeast chromosome telomere. Further biochemical studies showed that the SIR2 protein is a *histone deacetylase*; it removes acetyl groups on lysines of the histone tails. Also, the RAP1, and SIR2, 3, and 4 proteins bind to one another, and SIR3 and SIR4 bind to the N-terminal tails of histones H3 and H4 that are maintained in a largely unacetylated state by the deacetylase activity of SIR2. Several experiments using fluorescence confocal microscopy of yeast cells either stained with fluorescent-labeled antibody to any one of the SIR proteins or RAP1 or hybridized to a labeled telomere-specific DNA probe revealed that these proteins form large, condensed telomeric nucleoprotein structures resembling the heterochromatin found in higher eukaryotes (Figure 7-35a, b, c).

Figure 7-35d depicts a model for the chromatin-mediated silencing at yeast telomeres based on these and other studies. Formation of heterochromatin at telomeres is nucleated by multiple RAP1 proteins bound to repeated sequences in a nucleosome-free region at the extreme end of a telomere. A network of protein-protein interactions involving telomere-bound RAP1, three SIR proteins (2, 3, and 4), and hypoacetylated histones H3 and H4 creates a higher-order nucleoprotein

EXPERIMENTAL FIGURE 7-35 Antibody and DNA probes colocalize SIR3 protein with telomeric heterochromatin in yeast nuclei. (a) Confocal micrograph 0.3 mm thick through three diploid yeast cells, each containing 68 telomeres. Telomeres were labeled by hybridization to a fluorescent telomere-specific probe (yellow). DNA was stained red to reveal the nuclei. The 68 telomeres coalesce into a much smaller number of regions near the nuclear periphery. (b, c) Confocal micrographs of yeast cells labeled with a telomere-specific hybridization probe (b) and a fluorescent-labeled antibody specific for SIR3 (c). Note that SIR3 is localized in the repressed telomeric heterochromatin. Similar experiments with RAP1, SIR2, and SIR4 have shown that these proteins also colocalize with the repressed telomeric heterochromatin. (d) Schematic model of silencing mechanism at yeast telomeres. (Top left) Multiple copies of RAP1 bind to a simple repeated

sequence at each telomere region that lacks nucleosomes. SIR3 and SIR4 bind to RAP1, and SIR2 binds to SIR4. SIR2 is a histone deacetylase that deacetylates the tails on the histones neighboring the repeated RAP1-binding site. (Middle) The hypoacetylated histone tails are also binding sites for SIR3 and SIR4, which in turn bind additional SIR2, deacetylating neighboring histones. Repetition of this process results in spreading of the region of hypoacetylated histones with associated SIR2, SIR3, and SIR4. (Bottom) Interactions between complexes of SIR2, SIR3, and SIR4 cause the chromatin to condense and several telomeres to associate, as shown in a–c. The higher-order chromatin structure generated sterically blocks other proteins from interacting with the underlying DNA. [Parts (a)–(c) from M. Gotta et al., 1996, *J. Cell Biol.* **134**:1349; courtesy of M. Gotta, T. Laroche, and S. M. Gasser. Part (d) adapted from M. Grunstein, 1997, *Curr. Opin. Cell Biol.* **9**:383.]

complex that includes several telomeres and in which the DNA is largely inaccessible to external proteins. One additional protein, SIR1, is also required for silencing of the mating-type loci. It binds to the silencer regions associated with *HML* and *HMR* together with RAPI and other proteins to initiate assembly of a similar multiprotein silencing complex that encompasses *HML* and *HMR*.

An important feature of this model is the dependence of repression on *hypoacetylation* of the histone tails. This was shown in experiments with yeast mutants expressing histones in which lysines in histone N-termini were substituted with either arginines or glutamines or glycines. Arginine is positively charged like lysine but cannot be acetylated. Glutamine, on the other hand, is neutral and simulates the neutral charge of acetylated lysine, and glycine, with no side chain, also mimics the absence of a positively charged lysine. Repression at telomeres and at the silent mating-type loci was defective in the mutants with glutamine and glycine substitutions but not in mutants with arginine substitutions. Further, acetylation of H3 and H4 lysines interferes with binding by SIR3 and SIR4 and consequently prevents repression at the silent loci and telomeres. Finally, chromatin immunoprecipitation experiments (Figure 7-16a) using antibodies specific for acetylated lysines at particular positions in the histone N-terminal tails (Figure 6-31a) confirmed that histones in repressed regions near telomeres and at the silent mating loci are hypoacetylated, but become hyperacetylated in *sir* mutants when genes in these regions are derepressed.

Repressors Can Direct Histone Deacetylation at Specific Genes

The importance of *histone deacetylation* in chromatin-mediated gene repression was further supported by studies of eukaryotic repressors that regulate genes at internal chromosomal positions. These proteins are now known to act in part by causing deacetylation of histone tails in nucleosomes that bind to the TATA box and promoter-proximal region of the genes they repress. In vitro studies have shown that when promoter DNA is assembled onto a nucleosome with unacetylated histones, the general transcription factors cannot bind to the TATA box and initiation region. In unacetylated histones, the N-terminal lysines are positively charged and may interact with DNA phosphates. The unacetylated histone tails also interact with neighboring histone octamers and other chromatin-associated proteins, favoring the folding of chromatin into condensed, higher-order structures whose precise conformation is not well understood. The net effect is that general transcription factors cannot assemble into a preinitiation complex on a promoter associated with hypoacetylated histones. In contrast, binding of general transcription factors is repressed much less by histones with hyperacetylated tails in which the positively charged lysines are neutralized and electrostatic interactions are eliminated.

The connection between histone deacetylation and repression of transcription at specific yeast promoters became

clearer when the cDNA encoding a human *histone deacetylase* was found to have high homology to the yeast *RPD3* gene, known to be required for the normal repression of a number of yeast genes. Further work showed that RPD3 protein has histone deacetylase activity. The ability of RPD3 to deacetylate histones at a number of promoters depends on two other proteins: UME6, a repressor that binds to a specific upstream regulatory sequence (URS1), and SIN3, which is part of a large, multiprotein complex that also contains RPD3. SIN3 also binds to the repression domain of UME6, thus positioning the RPD3 histone deacetylase in the complex so it can interact with nearby promoter-associated nucleosomes and remove acetyl groups from histone tail lysines. Additional experiments, using the chromatin immunoprecipitation technique outlined in Figure 7-16a and antibodies to specific histone acetylated lysines demonstrated that in wild-type yeast, one or two nucleosomes in the immediate vicinity of UME6-binding sites are hypoacetylated. These DNA regions include the promoters of genes repressed by UME6. In *sin3* and *rpd3* deletion mutants, not only were these promoters derepressed, the nucleosomes near the UME6-binding sites were hyperacetylated.

All these findings provide considerable support for the model of repressor-directed deacetylation shown in Figure 7-36a. The SIN3-RPD3 complex functions as a *co-repressor*. Co-repressor complexes containing histone deacetylases also have been found associated with many repressors from mammalian cells. Some of these complexes contain the mammalian homolog of SIN3 (mSin3), which interacts with the repression domain of repressors, as in yeast. Other histone deacetylase complexes identified in mammalian cells appear to contain additional or different repression domain-binding proteins. These various repressor and co-repressor combinations mediate histone deacetylation at specific promoters by a mechanism similar to the yeast mechanism (see Figure 7-36a). In addition to repression through the formation of “closed” chromatin structures, some repression domains also inhibit the assembly of preinitiation complexes in in vitro experiments with purified general transcription factors in the absence of histones. This activity probably contributes to the repression of transcription by these repression domains in vivo as well.

Activators Can Direct Histone Acetylation at Specific Genes

Just as repressors function through co-repressors that bind to their repression domains, the activation domains of DNA-binding activators function by binding multisubunit *co-activator* complexes. One of the first co-activator complexes to be characterized was the yeast SAGA complex, which functions with the GCN4 activator protein described in Section 7.4. Early genetic studies indicated that full activity of the GCN4 activator required a protein called GCN5. The clue to GCN5's function came from biochemical studies of a *histone acetylase* purified from the protozoan *Tetrahymena*, the first histone acetylase to be purified. Sequence analysis revealed homology

(a) Repressor-directed histone deacetylation

(b) Activator-directed histone hyperacetylation

FIGURE 7-36 Proposed mechanism of histone deacetylation and hyperacetylation in yeast transcription control. (a) Repressor-directed deacetylation of histone N-terminal tails. The DNA-binding domain (DBD) of the repressor UME6 interacts with a specific upstream control element (URS1) of the genes it regulates. The UME6 repression domain (RD) binds SIN3, a subunit of a multiprotein complex that includes RPD3, a histone deacetylase. Deacetylation of histone N-terminal tails on nucleosomes in the region of the UME6-binding site inhibits binding of general transcription factors at the TATA box, thereby repressing gene expression. (b) Activator-directed hyperacetylation of histone N-terminal tails. The DNA-binding domain of the activator GCN4 interacts with specific upstream activating sequences (UAS) of the genes it regulates. The GCN4 activation domain (AD) then interacts with a multiprotein histone acetylase complex that includes the GCN5 catalytic subunit. Subsequent hyperacetylation of histone N-terminal tails on nucleosomes in the vicinity of the GCN4-binding site facilitates access of the general transcription factors required for initiation. Repression and activation of many genes in higher eukaryotes occurs by similar mechanisms.

between the *Tetrahymena* protein and yeast GCN5, which was soon shown to have histone acetylase activity as well. Further genetic and biochemical studies revealed that GCN5 is one subunit of a multiprotein co-activator complex, named the SAGA complex after genes encoding some of the subunits. Another subunit of this histone acetylase complex binds to activation domains in multiple yeast activator proteins, including GCN4. The model shown in Figure 7-36b is consistent with the observation that nucleosomes near the promoter region of a gene regulated by the GCN4 activator are specifically hyperacetylated compared to most histones in the cell. This activator-directed hyperacetylation of nucleosomes near a promoter region opens the chromatin structure so as to facilitate the binding of other proteins required for transcription initiation. The chromatin structure is less condensed compared to most chromatin, as indicated by its sensitivity to digestion with nucleases in isolated nuclei.

In addition to leading to the decondensation of chromatin, the acetylation of specific histone lysines generates binding sites for proteins with *bromodomains* that bind them. For example, a subunit of the general transcription factor TFIID contains two bromodomains that bind to acetylated nucleosomes with high affinity. Recall that TFIID binding to a promoter initiates assembly of an RNA polymerase II pre-

initiation complex (see Figure 7-17). Nucleosomes at promoter regions of virtually all active genes are hyperacetylated.

A similar activation mechanism operates in higher eukaryotes. Mammalian cells contain multisubunit histone acetylase co-activator complexes homologous to the yeast SAGA complex. They also express two related ≈ 300 -kDa, multidomain proteins called CBP and P300, which function similarly. As noted earlier, one domain of CBP binds the phosphorylated acidic activation domain in the CREB transcription factor. Other domains of CBP interact with different activation domains in other activators. Yet another domain of CBP has histone acetylase activity, and another CBP domain associates with additional multisubunit histone acetylase complexes. CREB and many other mammalian activators function in part by directing CBP and the associated histone acetylase complex to specific nucleosomes, where they acetylate histone tails, facilitating the interaction of general transcription factors with promoter DNA.

Chromatin-Remodeling Factors Help Activate or Repress Transcription

In addition to histone acetylase complexes, multiprotein chromatin-remodeling complexes also are required for activation

FIGURE 7-37 Expression of fusion proteins demonstrates chromatin decondensation in response to an activation domain.

A cultured hamster cell line was engineered to contain multiple copies of a tandem array of *E. coli* lac operator sequences integrated into a chromosome in a region of heterochromatin. (a) When an expression vector for the lac repressor was transfected into these cells, lac repressors bound to the lac operator sites could be visualized in a region of condensed chromatin using an antibody against the lac repressor (red). DNA was visualized by staining with DAPI (blue), revealing the nucleus. (b) When an expression vector for the lac repressor fused to an activation domain was transfected into these cells, staining as in (a) revealed that the activation domain causes this region of chromatin to decondense into a thinner chromatin fiber that fills a much larger volume of the nucleus. [Courtesy of Andrew S. Belmont, 1999, *J. Cell Biol.* 145:1341.]

at many promoters. The first of these characterized was the yeast SWI/SNF chromatin-remodeling complex. One of the SWI/SNF subunits has homology to DNA helicases, enzymes that use energy from ATP hydrolysis to disrupt interactions between base-paired nucleic acids or between nucleic acids and proteins. In vitro, the SWI/SNF complex is thought to pump or push DNA into the nucleosome so that DNA bound to the surface of the histone octamer transiently dissociates from the surface and translocates, causing the nucleosomes to “slide” along the DNA. The net result of such chromatin remodeling is to facilitate the binding of transcription factors to specific DNA sequences in chromatin. Many activation domains bind to chromatin-remodeling complexes, and this binding stimulates in vitro transcription from chromatin templates (DNA bound to nucleosomes). Thus the SWI/SNF complex represents another type of co-activator complex. The experiment shown in Figure 7-37 demonstrates dramatically how an activation domain can cause decondensation of a region of chromatin. This results from association of the activation domain with chromatin-remodeling and histone acetylase complexes.

Chromatin-remodeling complexes are required for many processes involving DNA in eukaryotic cells, including transcription control, DNA replication, recombination, and

DNA repair. Several types of chromatin-remodeling complexes are found in eukaryotic cells, all with homologous DNA helicase domains. SWI/SNF complexes and related chromatin-remodeling complexes in multicellular organisms contain subunits with bromodomains that bind to acetylated histone tails. Consequently, SWI/SNF complexes remain associated with activated, acetylated regions of chromatin, presumably maintaining them in a decondensed conformation. Chromatin-remodeling complexes can also participate in transcriptional repression. These chromatin-remodeling complexes bind to transcription repression domains of repressors and contribute to repression, presumably by folding chromatin into condensed structures. Much remains to be learned about how this important class of proteins alters chromatin structure to influence gene expression and other processes.

The Mediator Complex Forms a Molecular Bridge Between Activation Domains and Pol II

Once the interaction of activation domains with histone acetylase complexes and chromatin remodeling complexes converts the chromatin of a promoter region to an “open” chromatin structure that allows the binding of general transcription factors, activation domains interact with another multisubunit co-activator complex, the mediator (Figure 7-38). Activation domain–mediator interactions stimulate assembly of the pre-initiation complex on the promoter. The head and middle domains of the mediator complex are proposed to interact directly with subunits RBP3, 4, 7, and 11 of Pol II. Several mediator subunits bind to activation domains in various activator proteins. Thus mediator can form a molecular bridge between an activator bound to its cognate site in DNA and Pol II at a promoter.

Experiments with temperature-sensitive yeast mutants indicate that some mediator subunits are required for transcription of virtually all yeast genes. These subunits most likely help maintain the overall structure of the mediator complex or bind to Pol II and therefore are required for activation by all activators. In contrast, other mediator subunits are required for normal activation or repression of specific subsets of genes. DNA microarray analysis of yeast gene expression in mutants with defects in these mediator subunits indicates that each such subunit influences transcription of ≈ 3 –10 percent of all genes to the extent that its deletion either increases or decreases mRNA expression by a factor of twofold or more (see Figure 5-29 for DNA microarray technique). These mediator subunits are thought to interact with specific activation domains; thus when one subunit is defective, transcription of genes regulated by activators that bind to that subunit is severely depressed, but transcription of other genes is unaffected. Recent studies suggest that most activation domains may interact with more than one mediator subunit.

The various experimental results indicating that individual mediator subunits bind to specific activation domains suggest that multiple activators influence transcription from a single promoter by interacting with a mediator complex simultaneously

(a) Yeast mediator-Pol II complex

(b) *S. cerevisiae* mediator

(c) Human mediator

(Figure 7-39). Activators bound at enhancers or promoter-proximal elements can interact with mediator associated with a promoter because chromatin, like DNA, is flexible and can form a loop bringing the regulatory regions and the promoter close together, as observed for the *E. coli* NtrC activator and σ^{54} -RNA polymerase (see Figure 7-4). The multiprotein nucleoprotein complexes that form on eukaryotic promoters may comprise as many as 100 polypeptides with a total mass of ≈ 3 megadaltons (MDa), as large as a ribosome.

FIGURE 7-38 Structure of yeast and human mediator complexes. (a) Reconstructed image of mediator from *S. cerevisiae* bound to Pol II. Multiple electron microscopy images were aligned and computer-processed to produce this average image in which the three-dimensional Pol II structure (light orange) is shown associated with the yeast mediator complex (dark blue). (b) Diagrammatic representation of mediator subunits from *S. cerevisiae*. Subunits shown in the same color are thought to form a module. Mutations in one subunit of a module may inhibit association of other subunits in the same module with the rest of the complex. (c) Diagrammatic representation of human mediator subunits. The Yeast Two-Hybrid System

A powerful molecular genetic method called the *yeast two-hybrid system* exploits the flexibility in activator structures to identify genes whose products bind to a specific protein of interest. Because of the importance of protein-protein interactions in virtually every biological process, the yeast two-hybrid system is used widely in biological research.

This method employs a yeast vector for expressing a DNA-binding domain and flexible linker region without the

FIGURE 7-39 Model of several DNA-bound activators interacting with a single mediator complex. The ability of different mediator subunits to interact with specific activation domains may contribute to the integration of signals from several activators at a single promoter. See the text for discussion.

associated activation domain, such as the deleted GAL4-containing amino acids 1–692 (see Figure 7-26b). A cDNA sequence encoding a protein or protein domain of interest, called the *bait domain*, is fused in frame to the flexible linker region so that the vector will express a hybrid protein composed of the DNA-binding domain, linker region, and bait domain (Figure 7-40a, left). A cDNA library is cloned into multiple copies of a second yeast vector that encodes a strong activation domain and flexible linker to produce a vector library expressing multiple hybrid proteins, each containing a different *fish domain* (Figure 7-40a, right).

The bait vector and library of fish vectors are then transfected into engineered yeast cells in which the only copy of a gene required for histidine synthesis (*HIS*) is under control of a UAS with binding sites for the DNA-binding domain of the hybrid bait protein. Transcription of the *HIS* gene requires activation by proteins bound to the UAS. Transformed cells that express the bait hybrid and an *interacting* fish hybrid will be able to activate transcription of the *HIS* gene (Figure 7-40b). This system works because of the flexibility in the spacing between the DNA-binding and activation domains of eukaryotic activators.

A two-step selection process is used (Figure 7-40c). The bait vector also expresses a wild-type *TRP* gene, and the hybrid vector expresses a wild-type *LEU* gene. Transfected cells are first grown in a medium that lacks tryptophan and leucine but contains histidine. Only cells that have taken up the bait vector and one of the fish plasmids will survive in this medium. The cells that survive then are plated on a medium that lacks histidine. Those cells expressing a fish hybrid that does not bind to the bait hybrid cannot transcribe the *HIS* gene and consequently will not form a colony on medium lacking histidine. The few cells that express a bait-binding fish hybrid will grow and form colonies in the absence of histidine. Recovery of the fish vectors from these colonies

yields cDNAs encoding protein domains that interact with the bait domain.

KEY CONCEPTS of Section 7.5

Molecular Mechanisms of Transcription Repression and Activation

- Eukaryotic transcription activators and repressors exert their effects largely by binding to multisubunit co-activators or co-repressors that influence assembly of Pol II transcription preinitiation complexes either by modulating chromatin structure (indirect effect) or by interacting with Pol II and general transcription factors (direct effect).
- The DNA in condensed regions of chromatin (heterochromatin) is relatively inaccessible to transcription factors and other proteins, so that gene expression is repressed.
- The interactions of several proteins with each other and with the hypoacetylated N-terminal tails of histones H3 and H4 are responsible for the chromatin-mediated repression of transcription that occurs in the telomeres and the silent mating-type loci in *S. cerevisiae* (see Figure 7-35).
- Some repression domains function by interacting with co-repressors that are histone deacetylase complexes. The subsequent deacetylation of histone N-terminal tails in nucleosomes near the repressor-binding site inhibits interaction between the promoter DNA and general transcription factors, thereby repressing transcription initiation (see Figure 7-36a).
- Some activation domains function by binding multiprotein co-activator complexes such as histone acetylase complexes. The subsequent hyperacetylation of histone N-terminal tails in nucleosomes near the activator-binding site facilitates interactions between the promoter DNA and general transcription factors, thereby stimulating transcription initiation (see Figure 7-36b).
- SWI/SNF chromatin-remodeling factors constitute another type of co-activator. These multisubunit complexes can transiently dissociate DNA from histone cores in an ATP-dependent reaction and may also decondense regions of chromatin, thereby promoting the binding of DNA-binding proteins needed for initiation to occur at some promoters.
- Mediator, another type of co-activator, is an ≈ 30 -subunit complex that forms a molecular bridge between activation domains and RNA polymerase II by binding directly to the polymerase and activation domains. By binding to several different activators simultaneously, mediator probably helps integrate the effects of multiple activators on a single promoter (see Figure 7-39).
- Activators bound to a distant enhancer can interact with transcription factors bound to a promoter because DNA is flexible and the intervening DNA can form a large loop.
- The highly cooperative assembly of preinitiation complexes in vivo generally requires several activators. A cell must produce

TECHNIQUE ANIMATION: Yeast Two-Hybrid System

EXPERIMENTAL FIGURE 7-40 The yeast two-hybrid system provides a way of screening a cDNA library for clones encoding proteins that interact with a specific protein of interest. (a) Two vectors are constructed containing genes that encode hybrid (chimeric) proteins. In one vector (*left*), the coding sequence for the DNA-binding domain of a transcription factor is fused to the sequences for a known protein, referred to as the "bait" domain (light blue). The second vector (*right*) expresses an activation domain fused to a "fish" domain (green) that interacts with the bait domain. (b) If yeast cells are transformed with vectors expressing both hybrids, the bait and fish portions of the chimeric proteins interact to produce a functional transcriptional activator. In this example, the activator promotes transcription of a *HIS* gene. One end of this protein complex binds to the upstream activating sequence (UAS) of the *HIS3* gene; the other end, consisting of the activation domain, stimulates assembly of the transcription preinitiation complex at the promoter (yellow). (c) To screen a cDNA library for clones encoding proteins that interact with a particular bait protein of interest, the library is cloned into the vector encoding the activation domain so that hybrid proteins are expressed. The bait vector and fish vectors contain wild-type selectable genes (e.g., a *TRP* or *LEU* gene). The only transformed cells that survive the indicated selection scheme are those that express the bait hybrid and a fish hybrid that interacts with it. See the text for discussion. [See S. Fields and O. Song, 1989, *Nature* **340**:245.]

7.6 Regulation of Transcription-Factor Activity

We have seen in the preceding discussion how combinations of activators and repressors that bind to specific DNA regulatory sequences control transcription of eukaryotic genes. Whether or not a specific gene in a multicellular organism is expressed in a particular cell at a particular time is largely a consequence of the nuclear concentrations and activities of the transcription factors that interact with the regulatory sequences of that gene. (Exceptions are due to "transcriptional memory" of the functions of activators and repressors expressed in embryonic cells from which the cell has descended as the result of *epigenetic* mechanisms discussed in the next section.) Which transcription factors are expressed in a particular cell type, and the amounts produced, are determined by multiple regulatory interactions between transcription-factor genes that occur during the development and differentiation of a particular cell type.

In addition to controlling the expression of thousands of specific transcription factors, cells also regulate the activities of many of the transcription factors expressed in a particular cell type. For example, transcription factors are often regulated in response to extracellular signals. Interactions between the extracellular domains of transmembrane receptor proteins on the surface of the cell and specific protein ligands for these receptors activate protein domains associated with the intracellular domains of these transmembrane proteins,

the specific set of activators required for transcription of a particular gene in order to express that gene.

- The yeast two-hybrid system is widely used to detect cDNAs encoding protein domains that bind to a specific protein of interest (see Figure 7-40).

FIGURE 7-41 Examples of hormones that bind to **nuclear receptors**. These and related lipid-soluble hormones diffuse through the plasma and nuclear membranes and bind to receptors located in the cytosol or nucleus. The ligand-receptor complex functions as a transcription activator.

transducing the signal received on the outside of the cell to a signal on the inside of the cell that eventually reaches transcription factors in the nucleus. In Chapter 16, we describe the major types of cell-surface receptors and intracellular signaling pathways that regulate transcription-factor activity.

In this section, we discuss the second major group of extracellular signals, the small, lipid-soluble hormones—including many different steroid hormones, retinoids, and thyroid hormones—that can diffuse through plasma and nuclear membranes and interact directly with the transcription factors they control (Figure 7-41). As noted earlier, the intracellular receptors for most of these lipid-soluble hormones, which constitute the *nuclear-receptor superfamily*, function as transcription activators when bound to their ligands.

All Nuclear Receptors Share a Common Domain Structure

Sequencing of cDNAs derived from mRNAs encoding various nuclear receptors revealed a remarkable conservation in their amino acid sequences and three functional regions (Figure 7-42).

All the nuclear receptors have a unique N-terminal region of variable length (100–500 amino acids). Portions of this variable region function as activation domains in most nuclear receptors. The DNA-binding domain maps near the center of the primary sequence and has a repeat of the C₄ zinc-finger motif (Figure 7-29b). The hormone-binding domain, located near the C-terminal end, contains a hormone-dependent activation domain (see Figure 7-30b, c). In some nuclear receptors, the hormone-binding domain functions as a repression domain in the absence of ligand.

Nuclear-Receptor Response Elements Contain Inverted or Direct Repeats

The characteristic nucleotide sequences of the DNA sites, called *response elements*, that bind several nuclear receptors have been determined. The sequences of the consensus response elements for the glucocorticoid and estrogen receptors are 6-bp inverted repeats separated by any three base pairs (Figure 7-43a, b). This finding suggested that the cognate steroid hormone receptors would bind to DNA as symmetrical

FIGURE 7-42 General design of transcription factors in the **nuclear-receptor superfamily**. The centrally located DNA-binding domain exhibits considerable sequence homology among different receptors and contains two copies of the C₄ zinc-finger motif (see

Figure 7-29b). The C-terminal hormone-binding domain exhibits somewhat less homology. The N-terminal regions in various receptors vary in length, have unique sequences, and may contain one or more activation domains. [See R. M. Evans, 1988, *Science* **240**:889.]

FIGURE 7-43 Consensus sequences of DNA response elements that bind three nuclear receptors. The response elements for the glucocorticoid receptor (GRE) and estrogen receptor (ERE) contain inverted repeats that bind these homodimeric proteins. The response elements for heterodimeric receptors contain a common direct repeat separated by three to five base pairs for the vitamin D₃ receptor (VDRE), thyroid hormone receptor (TRE), and retinoic acid receptor (RARE). The repeat sequences are indicated by red arrows. [See K. Umesono et al., 1991, *Cell* **65**:1255, and A. M. Naar et al., 1991, *Cell* **65**:1267.]

dimers, as was later shown from the x-ray crystallographic analysis of the homodimeric glucocorticoid receptor's C₄ zinc-finger DNA-binding domain (see Figure 7-29b).

Some nuclear-receptor response elements, such as those for the receptors that bind vitamin D₃, thyroid hormone, and retinoic acid, are direct repeats of the same sequence recognized by the estrogen receptor, separated by three to five base pairs (Figure 7-43c–e). The specificity for responding to these different hormones by binding distinct receptors is determined by the spacing between the repeats. The receptors that bind to such direct-repeat response elements do so as heterodimers with a common nuclear-receptor monomer called RXR. The vitamin D₃ response element, for example, is bound by the RXR-VDR heterodimer, and the retinoic acid response element is bound by RXR-RAR. The monomers composing these heterodimers interact with each other in such a way that the two DNA-binding domains lie in the same rather than inverted orientation, allowing the RXR heterodimers to bind to direct repeats of the binding site for each monomer. In contrast, the monomers in homodimeric nuclear receptors (e.g., GRE and ERE) have an inverted orientation.

Hormone Binding to a Nuclear Receptor Regulates Its Activity as a Transcription Factor

The mechanism whereby hormone binding controls the activity of nuclear receptors differs for heterodimeric and homodimeric

receptors. Heterodimeric nuclear receptors (e.g., RXR-VDR, RXR-TR, and RXR-RAR) are located exclusively in the nucleus. In the absence of their hormone ligand, they repress transcription when bound to their cognate sites in DNA. They do so by directing histone deacetylation at nearby nucleosomes by the mechanism described earlier (see Figure 7-36a). In the ligand-bound conformation, heterodimeric nuclear receptors containing RXR can direct hyperacetylation of histones in nearby nucleosomes, thereby reversing the repressing effects of the free ligand-binding domain. In the presence of ligand, ligand-binding domains of nuclear receptors also bind mediator, stimulating preinitiation complex assembly.

In contrast to heterodimeric nuclear receptors, homodimeric receptors are found in the cytoplasm in the absence of their ligands. Hormone binding to these receptors leads to their translocation to the nucleus. The hormone-dependent translocation of the homodimeric glucocorticoid receptor (GR) was demonstrated in the transfection experiments shown in Figure 7-44. The GR hormone-binding domain alone mediates this transport. Subsequent studies showed that, in the absence of hormone, GR is anchored in the cytoplasm in a large protein complex with inhibitor proteins, including Hsp90, a protein related to Hsp70, the major heat-shock chaperone in eukaryotic cells. As long as the receptor is confined to the cytoplasm, it cannot interact with target genes and hence cannot activate transcription. Hormone binding to a homodimeric nuclear receptor releases the inhibitor proteins, allowing the receptor to enter the nucleus, where it can bind to response elements associated with target genes (Figure 7-44d). Once the receptor with bound hormone binds to a response element, it activates transcription by interacting with chromatin-remodeling and histone acetylase complexes and mediator.

Metazoans Regulate the Pol II Transition from Initiation to Elongation

A recent unexpected discovery that resulted from application of the chromatin immunoprecipitation technique is that a large fraction of genes in metazoans have a paused elongating Pol II within ≈200 base pairs of the transcription start site (Figure 7-16). Thus expression of the encoded protein is controlled not only by transcription initiation, but also by transcription elongation early in the transcription unit. The first genes discovered to be regulated by controlling transcription elongation were *heat-shock genes* (e.g., *hsp70*) encoding protein chaperonins that help to refold denatured proteins and other proteins that help the cell to deal with denatured proteins. When heat shock occurs, the heat-shock transcription factor (HSTF) is activated. Binding of activated HSTF to specific sites in the promoter-proximal region of heat-shock genes stimulates the paused polymerase to continue chain elongation and promotes rapid reinitiation by additional RNA polymerase II molecules, leading to many transcription initiations per minute. This mechanism of transcriptional control permits a rapid response: these genes are always paused in a state of suspended transcription and therefore, when an emergency arises, require no time to

EXPERIMENTAL FIGURE 7-44 Fusion proteins from expression vectors demonstrate that the hormone-binding domain of the glucocorticoid receptor (GR) mediates translocation to the nucleus in the presence of hormone. Cultured animal cells were transfected with expression vectors encoding the proteins diagrammed at the bottom.

Immunofluorescence with a labeled antibody specific for β -galactosidase was used to detect the expressed proteins in transfected cells. (a) In cells that expressed β -galactosidase alone, the enzyme was localized to the cytoplasm in the presence and absence of the glucocorticoid hormone dexamethasone (Dex). (b) In cells that expressed a fusion protein consisting of β -galactosidase and the entire glucocorticoid receptor (GR), the fusion protein was present in the cytoplasm in the absence of hormone but was transported to the nucleus in the presence of hormone. (c) Cells that expressed a fusion protein composed of β -galactosidase and just the GR ligand-binding domain (light purple) also exhibited hormone-dependent transport of the fusion protein to the nucleus. (d) Model of hormone-dependent gene activation by a homodimeric nuclear receptor. In the absence of hormone, the receptor is kept in the cytoplasm by interaction between its ligand-binding domain (LBD) and inhibitor proteins. When hormone is present, it diffuses through the plasma membrane and binds to the ligand-binding domain, causing a conformational change that releases the receptor from the inhibitor proteins. The receptor with bound ligand is then translocated into the nucleus, where its DNA-binding domain (DBD) binds to response elements, allowing the ligand-binding domain and an additional activation domain (AD) at the N-terminus to stimulate transcription of target genes. [Parts (a)–(c) from D. Picard and K. R. Yamamoto, 1987, *EMBO J.* 6:3333; courtesy of the authors.]

capable of differentiation into any cell type. The ability to induce differentiated cells to convert to pluripotent stem cells has elicited enormous research interest because of its potential for the development of therapeutic treatments for traumatic injuries to the nervous system and degenerative diseases (Chapter 21).

Pol II Termination Is Also Regulated

Once Pol II has transcribed ≈ 200 nucleotides from the transcription start site, elongation through most genes is highly processive, although the chromatin immunoprecipitation with antibody to Pol II indicates that the amount of Pol II at various positions in a transcription unit in a population of cells varies greatly (Figure 7-16b, right). This indicates that the enzyme can elongate through some regions much more rapidly than others. In most cases, Pol II does not terminate until after a sequence is transcribed that directs cleavage and

remodel and acetylate chromatin over the promoter and assemble a transcription preinitiation complex.

Another transcription factor shown to regulate transcription by controlling elongation of Pol II paused near the transcription start site is MYC, which functions in the regulation of cell growth and division. MYC is often expressed at high level in cancer cells and is a key transcription factor in the reprogramming of somatic cells into pluripotent stem cells

polyadenylation of the RNA at the sequence that forms the 3' end of the encoded mRNA. RNA polymerase II then can terminate at multiple sites located over a distance of 0.5–2 kb beyond this poly(A) addition site. Experiments with mutant genes show that termination is coupled to the process that cleaves and polyadenylates the 3' end of a transcript, which is discussed in the next chapter.

KEY CONCEPTS of Section 7.6

Regulation of Transcription-Factor Activity

- The activities of many transcription factors are indirectly regulated by binding of extracellular proteins and peptides to cell-surface receptors. These receptors activate intracellular signal-transduction pathways that regulate specific transcription factors through a variety of mechanisms discussed in Chapter 16.
- Nuclear receptors constitute a superfamily of dimeric C₄ zinc-finger transcription factors that bind lipid-soluble hormones and interact with specific response elements in DNA (see Figures 7-41-43).
- Hormone binding to nuclear receptors induces conformational changes that modify their interactions with other proteins (Figure 7-30b, c).
- Heterodimeric nuclear receptors (e.g., those for retinoids, vitamin D, and thyroid hormone) are found only in the nucleus. In the absence of hormone, they repress transcription of target genes with the corresponding response element. When bound to their ligands, they activate transcription.
- Steroid hormone receptors are homodimeric nuclear receptors. In the absence of hormone, they are trapped in the cytoplasm by inhibitor proteins. When bound to their ligands, they can translocate to the nucleus and activate transcription of target genes (see Figure 7-44).

7.7 Epigenetic Regulation of Transcription

The term **epigenetic** refers to inherited changes in the phenotype of a cell that do not result from changes in DNA sequence. For example, during the differentiation of bone marrow stem cells into the several different types of blood cells, a hematopoietic stem cell (HSC) divides into two daughter cells, one of which continues to have the properties of an HSC with the potential to differentiate into all of the different types of blood cells. But the other daughter cell becomes either a lymphoid stem cell or a myeloid stem cell (see Figure 21-18). Lymphoid stem cells generate daughter cells that differentiate into lymphocytes, which perform many of the functions involved in immune responses to pathogens (Chapter 23). Myeloid stem cells divide into daughter cells that are committed to differentiating into red blood cells, different kinds of phagocytic white

blood cells, or the cells that generate platelets involved in blood clotting. Lymphoid and myeloid stem cells both have the identical DNA sequence as the zygote generated by fertilization of the egg cell by a sperm cell from which all cells develop, but they have restricted developmental potential because of epigenetic differences between them. Such epigenetic changes are initially the consequence of the expression of specific transcription factors that are master regulators of cellular differentiation, controlling the expression of other genes encoding transcription factors and proteins involved in cell-cell communication in complex networks of gene control that are currently the subject of intense investigation. Changes in gene expression initiated by transcription factors are often reinforced and maintained over multiple cell divisions by post-translational modifications of histones and methylation of DNA at position 5 of the cytosine pyrimidine ring (Figure 2-17) that are maintained and propagated to daughter cells when cells divide. Consequently, the term **epigenetic** is used to refer to such post-translational modifications of histones and 5-methyl C modification of DNA.

Epigenetic Repression by DNA Methylation

As mentioned earlier, most promoters in mammals fall into the CpG island class. Active CpG island promoters have Cs in CG sequences that are unmethylated. Unmethylated CpG island promoters are generally depleted of histone octamers, but nucleosomes immediately neighboring the unmethylated CpG island promoters are modified by histone H3 lysine 4 di- or trimethylation and have associated Pol II molecules that are paused during transcription of both the sense and non-sense template DNA strands, as discussed earlier (Figures 7-16 and 17). Recent research indicates that methylation of histone H3 lysine 4 occurs in mouse cells because a protein named Cfp1 (CXXC finger protein 1) binds unmethylated CpG-rich DNA through a zinc-finger domain (CXXC) and associates with a histone methylase specific for histone H3 lysine 4 (Setd1). Chromatin-remodeling complexes and the general transcription factor TFIID, which initiates Pol II preinitiation complex assembly (Figure 7-17), associate with nucleosomes bearing the H3 lysine 4 trimethyl mark, promoting Pol II transcription initiation.

However, in differentiated cells, a few percent of specific CpG island promoters, depending on the cell type, have CpGs marked by 5-methyl C. This modification of CpG island DNA triggers chromatin condensation. A family of proteins that bind to DNA rich in 5 methyl-C modified CpGs (methyl CpG-binding proteins, MBDs) associate with histone deacetylases and repress chromatin-remodeling complexes that condense chromatin, resulting in transcriptional repression. These methyl groups are added by *de novo* DNA methyl transferases named DNMT3a and DNMT3b. Much remains to be learned about how these enzymes are directed to specific CpG islands, but once they have methylated a DNA sequence, methylation is passed on through DNA replication through the action of the ubiquitous *maintenance* methyl transferase DNMT1:

(Red indicates daughter strands.) DNMT1 also maintains methylation of the Cs in CpG sequences that are statistically underrepresented throughout most of the genome. As discussed above, the CG sequence is underrepresented in most of the sequence of mammalian genomes, probably because spontaneous deamination of 5-methyl C generates thymidine, leading to the substitution of CpGs with TpGs over the period of mammalian evolution, unless there is selection against the resulting mutation, as probably occurs when CpG island promoters are mutated. This mechanism of epigenetic repression is intensely investigated because tumor-suppressor genes encoding proteins that function to suppress the development of cancer are often inactivated in cancer cells by abnormal CpG methylation of their promoter regions, as discussed further in Chapter 24.

Histone Methylation at Other Specific Lysines Are Linked to Epigenetic Mechanisms of Gene Repression

Figure 6-31b summarizes the different types of post-translational modifications that are found on histones, including acetylation of lysines and methylation of lysines on the nitrogen atom of the terminal ϵ -amino group of the lysine

side chain (see Figure 2-14). Lysines can be modified by the addition of one, two, or three methyl groups to this terminal nitrogen atom, generating mono-, di-, and trimethylated lysine, all of which carry a single positive charge. Pulse-chase radiolabeling experiments have shown that acetyl groups on histone lysines turn over rapidly, whereas methyl groups are much more stable. The acetylation state at a specific histone lysine on a particular nucleosome results from a dynamic equilibrium between acetylation and deacetylation by histone acetylases and histone deacetylases, respectively. Acetylation of histones in a localized region of chromatin predominates when local DNA-bound activators transiently bind histone acetylase complexes. De-acetylation predominates when repressors transiently bind histone deacetylase complexes.

In contrast to acetyl groups, methyl groups on histone lysines are much more stable and turn over much less rapidly than acetyl groups. Histone lysine methyl groups can be removed by *histone lysine demethylases*. But the resulting turnover of histone lysine methyl groups is much slower than the turnover of histone lysine acetyl groups, making them appropriate post-translational modifications for propagating epigenetic information. Several other post-translational modifications have been characterized on histones (Figure 6-31b). These all have the potential to positively or

TABLE 7-3 Histone Post-Translational Modifications Associated with Active and Repressed Genes

Modification	Sites of Modification	Effect on Transcription
Acetylated lysine	H3 (K9, K14, K18, K27, K56) H4 (K5, K8, K13, K16) H2A (K5, K9, K13) H2B (K5, K12, K15, K20)	Activation

negatively regulate the binding of proteins that interact with the chromatin fiber to regulate transcription and other processes such as chromosome folding into the highly condensed structures that form during mitosis (Figures 6-39 and 6-40). A picture of chromatin has emerged in which histone tails extending as random coils from the chromatin fiber are post-translationally modified to generate one of many possible combinations of modifications that regulate transcription and other processes by regulating the binding of a large number of different protein complexes. This control of protein interactions with specific regions of chromatin resulting from the combined influences of various post-translational modifications of histones has been called a *histone code*. Some of these modifications, such as histone lysine acetylation, are rapidly reversible, whereas others, such as histone lysine methylation, can be templated through chromatin replication, generating epigenetic inheritance in addition to inheritance of DNA sequence. Table 7-3 summarizes the influence that post-translational modifications of specific histone amino acid residues usually have in transcription.

Histone H3 Lysine 9 Methylation in Heterochromatin In most eukaryotes, some co-repressor complexes contain histone

methyl transferase subunits that methylate histone H3 at lysine 9, generating di- and trimethyl lysines. These methylated lysines are binding sites for isoforms of HP1 protein that function in the condensation of heterochromatin, as discussed in Chapter 6 (see Figure 6-34). For example, the KAP1 co-repressor complex functions with a class of more than 200 zinc-finger transcription factors encoded in the human genome. This co-repressor complex includes an H3 lysine 9 methyl transferase that methylates nucleosomes over the promoter region of repressed genes, leading to HP1 binding and repression of transcription. An integrated transgene in cultured mouse fibroblasts that was repressed through the action of the KAP1 co-repressor associated with heterochromatin in most cells, whereas the active form of the same transgene associated with euchromatin (Figure 7-45). Chromatin immunoprecipitation assays (see Figure 7-16) showed that the repressed gene was associated with histone H3 methylated at lysine 9 and HP1, whereas the active gene was not.

Importantly, H3 lysine 9 methylation is maintained following chromosome replication in S phase by the mechanism diagrammed in Figure 7-46. When chromosomes replicate in S phase, the nucleosomes associated with the parental DNA are randomly distributed to the daughter DNA molecules. New

FIGURE 7-45 Association of a repressed transgene with heterochromatin. Mouse fibroblasts were stably transformed with a transgene with binding sites for an engineered repressor. The repressor was a fusion between a DNA-binding domain, a repression domain that interacts with the KAP1 co-repressor complex, and the ligand-binding domain of a nuclear receptor that allows the nuclear import of the fusion protein to be controlled experimentally (see Figure 7-44). DNA was stained blue with the dye DAPI. Brighter-staining regions are regions of heterochromatin, where the DNA concentration is higher than in euchromatin. The transgene was detected by hybridization of a

fluorescently labeled complementary probe (green). When the recombinant repressor was retained in the cytoplasm, the transgene was transcribed (*left*) and was associated with euchromatin in most cells. When hormone was added so that the recombinant repressor entered the nucleus, the transgene was repressed (*right*) and associated with heterochromatin. Chromatin immunoprecipitation assays (see Figure 7-16) showed that the repressed gene was associated with histone H3 methylated at lysine 9 and HP1, whereas the active gene was not. [Courtesy of Frank Rauscher, from Ayyanathan et al., 2003, *Genes Dev.* 17:1855.]

FIGURE 7-46 Maintenance of histone H3 lysine 9 methylation during chromosome replication. When chromosomal DNA is replicated, the parental histones randomly associate with the two daughter DNA molecules while unmethylated histones synthesized during S phase comprise other nucleosomes on the sister chromosomes. Association of histone H3 lysine 9 methyl transferases (H3K9 HMT) with parental nucleosomes bearing the histone 3 lysine 9 di- or trimethylation mark methylate the newly added unmethylated nucleosomes. Consequently, histone H3 lysine 9 methylations are maintained during repeated cell divisions unless they are specifically removed by a histone demethylase.

histone octamers that are not methylated on lysine 9 associate with the new daughter chromosomes, but since the parental nucleosomes are associated with both daughter chromosomes, approximately half of them are methylated on lysine 9. Association of histone H3 lysine methyl transferases (directly or indirectly) with the parental methylated nucleosomes leads to methylation of the newly assembled histone octamers. Repetition of this process with each cell division results in maintenance of H3 lysine 9 methylation of this region of the chromosome.

Epigenetic Control by Polycomb and Trithorax Complexes

Another kind of epigenetic mark that is essential for repression of genes in specific cell types in multicellular animals and plants involves a set of proteins known collectively as Polycomb proteins and a counteracting set of proteins known as Trithorax proteins, after phenotypes of mutations in the genes encoding them in *Drosophila*, where they were first discovered. The Polycomb repression mechanism is essential for maintaining the repression of genes in specific types of cells and in all of the subsequent cells that develop from them throughout the life of an organism. Important genes regulated by Polycomb proteins include the *Hox* genes, encoding master regulatory transcription factors. Different

combinations of *Hox* transcription factors help to direct the development of specific tissues and organs in a developing embryo. Early in embryogenesis, expression of *Hox* genes is controlled by typical activator and repressor proteins. However, the expression of these activators and repressors stops at an early point in embryogenesis. Correct expression of the *Hox* genes in the descendants of the early embryonic cells is then maintained throughout the remainder of embryogenesis and on into adult life by the Polycomb proteins which maintain the *repression* of specific *Hox* genes. Trithorax proteins perform the opposing function to Polycomb proteins, maintaining the *expression* of the *Hox* genes that were expressed in a specific cell early in embryogenesis and in all the subsequent descendants of that cell. Polycomb and Trithorax proteins control thousands of genes, including genes that regulate cell growth and division (i.e., the cell cycle, as discussed in Chapter 19). Polycomb and Trithorax genes are often mutated in cancer cells, contributing importantly to the abnormal properties of these cells (Chapter 24).

Remarkably, virtually all cells in the developing embryo and adult express a similar set of Polycomb and Trithorax proteins, and all cells contain the same set of *Hox* genes. Yet only the *Hox* genes in cells where they were initially repressed in early embryogenesis remain repressed, even though the same *Hox* genes in other cells remain active in the presence of the same Polycomb proteins. Consequently, as in the case of the yeast silent mating-type loci, the expression of *Hox* genes is regulated by a process that involves more than simply specific DNA sequences interacting with proteins that diffuse through the nucleoplasm.

A current model for repression by Polycomb proteins is depicted in Figure 7-47. Most Polycomb proteins are subunits of one of two classes of multiprotein complexes, PRC1-type complexes and PRC2 complexes. PRC2 complexes are thought to act initially by associating with specific repressors bound to their cognate DNA sequences early in embryogenesis, or ribonucleoprotein complexes containing long non-coding RNAs as discussed in a later section. The PRC2 complexes contain histone deacetylases that inhibit transcription as discussed above. They also contain a subunit [E(z) in *Drosophila*, EZH2 in mammals] with a SET domain, the enzymatically active domain of several histone methyl transferases. This SET domain in PRC2 complexes methylates histone H3 on lysine 27, generating di- and trimethyl lysines. The PRC1 complex then binds the methylated nucleosomes through dimeric Pc subunits (CBXs in mammals), each containing a methyl-lysine binding domain (called a *chromodomain*) specific for methylated H3 lysine 27. Binding of the dimeric Pc to neighboring nucleosomes is proposed to condense the chromatin into a structure that inhibits transcription. This is supported by electron microscopy studies showing that PRC1 complexes cause nucleosomes to associate in vitro (Figure 7-47d, e).

PRC1 complexes also contain a ubiquitin ligase that monoubiquitinates histone H2A at lysine 119 in the H2A C-terminal tail. This modification of H2A inhibits Pol II elongation through chromatin by inhibiting the association

FIGURE 7-47 Model for repression by Polycomb complexes.

(a) During early embryogenesis, repressors associate with the PRC2 complex. (b) This results in methylation (Me) of neighboring nucleosomes on histone H3 lysine 27 (K27) by the SET-domain-containing subunit E(z). (c) The PRC1 complexes bind nucleosomes methylated at H3 lysine 27 through a dimeric, chromodomain-containing subunit Pc. The PRC1 complex condenses the chromatin into a repressed chromatin structure. PRC2 complexes associate with PRC1 complexes to

maintain H3 lysine 27 methylation of neighboring histones. As a consequence, PRC1 and PRC2 association with the region is maintained when expression of the repressor proteins in (a) ceases. (d, e) Electron micrograph of an ≈ 1 -kb fragment of DNA bound by four nucleosomes in the absence (d) and presence (e) of one PRC1 complex per five nucleosomes. [Parts (a)–(c), adapted from A. H. Lund and M. van Lohuizen, 2004, *Curr. Opin. Cell Biol.* **16**:239. Parts (d, e), from N. J. Francis, R. E. Kingston, and C. L. Woodcock, 2004, *Science* **306**:1574.]

of a histone chaperone required to remove histone octamers from DNA as Pol II transcribes through a nucleosome and then replaces them as the polymerase passes. PRC2 complexes are postulated to associate with nucleosomes bearing the histone H3 lysine 27 trimethylation mark, maintaining methylation of H3 lysine 27 in nucleosomes in the region. This results in association of the chromatin with PRC1 and PRC2 complexes even after expression of the initial repressor proteins in Figure 7-47a, b has ceased. This would also maintain histone H3 lysine 27 methylation and histone H2A monoubiquitination following DNA replication, by a mechanism analogous to that diagrammed in Figure 7-46. This is a key feature of Polycomb repression, which is maintained through successive cell divisions for the life of an organism (≈ 100 years for some vertebrates, 2000 years for a sugar cone pine!).

Trithorax proteins counteract the repressive mechanism of Polycomb proteins, as shown in studies of expression of the Hox transcription factor Abd-B in the *Drosophila* embryo (Figure 7-48). When the Polycomb system is defective, Abd-B is derepressed in all cells of the embryo. When the Trithorax system is defective and cannot counteract repression by the Polycomb system, Abd-B is repressed in most cells, except those in the very posterior of the embryo. Trithorax complexes include a histone methyl transferase that trimeth-

ylates histone H3 lysine 4, a histone methylation associated with the promoters of actively transcribed genes. This histone modification creates a binding site for histone acetylase and chromatin-remodeling complexes that promote transcription, as well as TFIID, the general transcription factor that initiates preinitiation-complex assembly (Figure 7-17). Nucleosomes with the H3 lysine 4 methyl modifications are also binding sites for specific histone demethylases that prevent methylation of histone H3 at lysine 9, preventing the binding of HP1, and at lysine 27, preventing the binding of the PRC-repressing complexes. Likewise, a histone demethylase specific for histone H3 lysine 4 associates with PRC2 complexes. Nucleosomes marked with histone H3 lysine 4 methylation also are thought to be distributed to both daughter DNA molecules during DNA replication, resulting in maintenance of this epigenetic mark by a strategy similar to that diagrammed in Figure 7-46.

Noncoding RNAs Direct Epigenetic Repression in Metazoans

Repressing complexes also have been discovered that are complexes of proteins bound to RNA molecules. In some cases, this results in repression of genes on the same chromosome from

FIGURE 7-48 Opposing influence of Polycomb and Trithorax complexes on expression of the Hox transcription factor Abd-B in *Drosophila* embryos. At the stage of *Drosophila* embryogenesis shown, Abd-B is normally expressed only in posterior segments of the developing embryo, as shown at the top by immunostaining with a specific anti-Abd-B antibody. In embryos with homozygous mutations of *Scm*, a Polycomb gene (PcG) encoding a protein associated with the PRC1 complex, Abd-B expression is de-repressed in all embryo segments. In contrast, in homozygous mutants of *trx*, a Trithorax gene (*trxG*), Abd-B repression is increased so that it is only expressed to high level in the most posterior segment. [Courtesy of Juerg Mueller, European Molecular Biology Laboratory.]

which the RNA is transcribed, as in the case of X-chromosome inactivation in female mammals. In other cases, these repressing RNA-protein complexes can be targeted to genes transcribed from other chromosomes by base-pairing with nascent RNAs as they are being transcribed.

X-Chromosome Inactivation in Mammals The phenomenon of X-chromosome inactivation in female mammals is one of the most intensely studied examples of epigenetic repression mediated by a long, non-protein-coding RNA. X inactivation is controlled by an ≈ 100 -kb domain on the X chromosome called the X-inactivation center. Remarkably, the X-inactivation center does not express proteins, but rather several noncoding RNAs (ncRNAs) that participate in the random inactivation of one entire X chromosome early in the development of female mammals. The ncRNAs whose functions are partially understood are transcribed from the complementary DNA strands near the middle of the X-inactivation center: the 40-kb *Tsix* RNA, the *Xist* RNA which is spliced into an RNA of ≈ 17 kb, and the shorter 1.6-kb *RepA* RNA from the 5' region of the *Xist* RNA (Figure 7-49a).

FIGURE 7-49 The *Xist* noncoding RNA encoded in the X-inactivation center coats the inactive X chromosome in cells of human females. (a) The region of the human X-inactivation center encoding the noncoding RNAs *Xist*, *RepA*, and *Tsix*. (b) A cultured fibroblast from a female was analyzed by in situ hybridization with a probe complementary to *Xist* RNA labeled with a red fluorescent dye (left), a chromosome paint set of probes for the X chromosome labeled with a green fluorescent dye (center), and an overlay of the two fluorescent micrographs. The condensed inactive X chromosome is associated with *Xist* RNA. [Part (a) adapted from J. T. Lee, 2010, *Cold Spring Harbor Perspect. Biol.* 2:a003749. Part (b) from C. M. Clemson et al., 1996, *J. Cell Biol.* 132:259.]

In differentiated female cells, the inactive X chromosome is associated with *Xist* RNA-protein complexes along its entire length. Targeted deletion of the *Xist* gene (Figure 5-42) in cultured embryonic stem cells showed that it is required for X inactivation. As opposed to most protein-coding genes on the inactive X chromosome, *Xist* is transcribed from the X-inactivation center of the otherwise mostly inactive X chromosome. The *Xist* RNA-protein complexes do not diffuse to interact with the active X chromosome, but remain associated with the inactive X chromosome. Since the full length of the inactive X becomes coated by *Xist* RNA-protein complexes (Figure 7-49b), these complexes must spread along the chromosome from the X-inactivation center where *Xist* is transcribed. The inactive X chromosome is also associated with Polycomb PRC2 complexes that catalyze the trimethylation of histone H3 lysine 27. This results in association of the PRC1 complex and transcriptional repression as discussed above.

In the early female embryo comprised of embryonic stem cells capable of differentiating into all cell types (see Chapter 21), genes on both X chromosomes are transcribed and the 40-kb *Tsix* ncRNA is transcribed from the X-inactivation center of both copies of the X chromosome. Experiments employing engineered deletions in the X-inactivation center have shown that *Tsix* transcription prevents significant transcription of the 17-kb *Xist* RNA from the complementary DNA strand. Later in development of the early embryo, as cells begin to differentiate, *Tsix* becomes transcribed only from the active X chromosome. The mechanism(s) controlling

this asymmetric transcription of Tsix are not yet understood. However, the process occurs randomly on the two X chromosomes.

In a current model of X inactivation, inhibition of Tsix transcription allows transcription of RepA RNA from the complementary DNA strand (Figure 7-49a). RepA RNA has a repeating sequence that forms stem-loop secondary structures that are bound directly by subunits of the Polycomb PRC2 complex. This interaction occurs on nascent RepA transcripts that are tethered to the X chromosome during transcription and leads to methylation of histone H3 at lysine 27 in the surrounding chromatin. By mechanisms that are not yet understood, this activates transcription from the nearby Xist promoter. The transcribed Xist RNA contains RNA sequences that by unknown mechanisms cause it to spread along the X chromosome. The RepA repeated sequence near the 5' end of the Xist RNA binds the PRC2 polycomb complex leading to H3K27 di- and trimethylation along the entire length of the X chromosome. This in turn results in binding of the PRC1 polycomb complex and transcriptional repression as discussed earlier. At the same time, continued transcription of Tsix from the other, active X chromosome continues, represses Xist transcription from that X chromosome, and consequently prevents Xist-mediated repression of the active X. A short time later in development, the DNA of the inactive X also becomes methylated at most of its associated CpG island promoters, probably contributing to its stable inactivation through the multiple cell divisions that occur later during embryogenesis and throughout adult life.

Trans Repression by Long Noncoding RNAs Another example of transcriptional repression by a long noncoding RNA was discovered recently by researchers studying the function of noncoding RNAs transcribed from a region encoding a cluster of *HOX* genes, the *HOXC* locus, in cultured human fibroblasts. Depletion of a 2.2-kb noncoding RNA expressed from the *HOXC* locus by siRNA (Figure 5-45) unexpectedly led to de-repression of the *HOXD* locus in these cells, an ≈40-kb region on another chromosome encoding several *HOX* proteins and multiple other noncoding RNAs. Assays similar to chromatin immunoprecipitation showed that this noncoding RNA, named HOTAIR for *HOX* Antisense Intergenic RNA, associates with the *HOXD* loci and with Polycomb PRC2 complexes. This results in histone H3 lysine 27 di- and trimethylation, PRC1 association, histone H3 lysine 4 demethylation, and transcriptional repression. This is similar to the recruitment of Polycomb complexes by Xist RNA except that Xist RNA functions *in cis*, remaining in association with the chromosome from which it is transcribed, whereas HOTAIR leads to Polycomb repression *in trans* on both copies of another chromosome.

Recently, characterization of DNA associated with the histone H3 lysine 4 trimethylation mark associated with promoter regions and H3 lysine 36 methylation associated with Pol II transcriptional elongation led to the discovery of ≈1600 long noncoding RNAs transcribed from intergenic regions between protein-coding genes that are evolutionarily

conserved between mammals. This conservation of sequence strongly suggests that these noncoding RNAs have important functions. The examples of Xist, HOTAIR, and two other recently discovered ncRNAs that target Polycomb repression mechanisms to specific genes raise the possibility that many of these may also target Polycomb repression. Consequently, the study of these conserved noncoding RNAs is another area of intense current investigation.

Plants and Fission Yeast Use Short RNA-Directed Methylation of Histones and DNA

Centromeres (Figure 6-45c) of the fission yeast *Schizosaccharomyces pombe* are composed of multiple sequence repeats as they are in multicellular organisms. Proper functioning of these centromeres during chromosome segregation in mitosis and meiosis (Figures 18-36, 5-10a, 19-38) requires centromeres to form heterochromatin. Heterochromatin formation at *S. pombe* centromeres is directed by short interfering RNAs (siRNAs), initially discovered in *C. elegans* for their function in the cytoplasm, where they direct degradation of mRNAs to which they hybridize (Figure 5-45 and discussed further in Chapter 8). RNA polymerase II transcribes low levels of noncoding transcripts from the centromeric repeats (cenRNA, Figure 7-50). This is converted into double-stranded RNA by an RNA-dependent RNA polymerase found in plants and many fungi (but not in the budding yeast *S. cerevisiae*, where the siRNA system does not occur, and not in mammals, where this mechanism of transcriptional repression may not occur). The resulting long double-stranded RNAs are cleaved by a double-strand RNA specific ribonuclease called *Dicer* into 22-nucleotide fragments with two-nucleotide 3' overhangs. One strand of these Dicer fragments is bound by a member of a protein family called *Argonaut* proteins that associate with siRNAs in both translational and transcriptional repression mechanisms. The *S. pombe* Argonaut protein, Ago1, associates with two other proteins to form the RITS complex (for RNA-induced transcriptional silencing).

The RITS complex associates with centromeric regions by base-pairing between the siRNA associated with its Ago1 subunit and nascent transcripts from the region and interactions of its Chp1 (chromodomain protein 1) subunit which contains a methyl lysine-binding chromodomain specific for binding histone H3 di- and trimethyl lysine 9 associated with heterochromatin. The RITS complex also associates with an RNA-dependent RNA polymerase-containing complex, RDRC. Since multiple siRNAs are generated from the double-stranded RNA, this results in a positive feedback loop that increases the association of RITS complexes with centromeric heterochromatin. The RITS complex also associates with a histone H3 lysine 9 methyl transferase. The resulting histone H3 lysine 9 methyl marks on the centromeric chromatin are binding sites for *S. pombe* HP1 proteins and a histone deacetylase (HDAC), leading to the condensation of the centromere region into heterochromatin.

FIGURE 7-50 Model for the generation of heterochromatin at *S. pombe* centromeres by noncoding RNAs. Step (1): Pol II transcripts of the repeated nonprotein-coding sequences of the centromere are transcribed at a low level. Step (2): The nascent RNA is bound by the RITS complex by base-pairing of the complementary short interfering RNA (siRNA) associated with the Ago1 subunit of the RITS complex and the interaction of the Chp1 subunit with histone H3 methylated on lysine 9. Step (3): The RITS complex associates with the RDRC complex, which includes an RNA-dependent RNA polymerase that converts the nascent Pol II transcript into double-stranded RNA. Step (4): The double-stranded RNA is cleaved by the Dicer double-strand-specific ribonuclease into double-stranded fragments of ≈ 22

nucleotides with two base overhangs at the 3' end of each strand. Step (5): One of the two ≈ 22 nucleotide strands generated is bound by the Ago1 subunit of a RITS complex. Since multiple siRNAs associated with RITS complexes are generated from each Pol II transcript, this results in a positive-feedback loop that concentrates RITS complexes at the centromere region. Step (6): The RITS complex also associates with a histone H3 lysine 9 methyl transferase (H3K9 HMT), which methylates histone H3 in the centromeric region. This generates a binding site for *S. pombe* HP1 proteins, as well as the Chp1 subunit of the RITS complex. Binding of HP1 condenses the region into heterochromatin as diagrammed in Figure 6-35a. [Adapted from D. Moazed, 2009, *Nature* 457:413.]

5-Methyl C Induction by ncRNAs in Plants The model plant *Arabidopsis thaliana* uses DNA methylation extensively to repress transcription of transposons and retrotransposons (discussed in Chapter 6) and certain specific genes. In addition to methylating C at the 5 position in the sequence CG, plants also methylate genes at CHG (where H is any of the other nucleotides) and CHH. There is a degree of redundancy, but the DNA methyl transferase MET1 largely carries out CpG methylation and is functionally similar to DNMT1 in multicellular animals. CMT3 (chromomethylase 3) methylates CHG, and DRM2 is the primary methyl transferase of CHH. Methylation of CpG and CHG sequences are maintained following DNA replication by MET1 and CMT3, respectively, by recognition of the methyl C in the parental strand of newly replicated DNA and methylation of the daughter strand C, as discussed above for human DNMT1. However, one of the daughter chromosomes of a CHH methylation site has an unmodified G at the position complementary to the methylated C, and hence carries no DNA modification that can be recognized by the DRM2 methyl transferase. Consequently, CHH methylation sites must be maintained through cell division by an alternative mechanism.

The *FWA* gene encodes a homeodomain transcription factor involved in regulation of the flowering time in response to temperature, so that plants do not flower until the warm days of spring. In wild-type *A. thaliana*, *FWA* is repressed by CHH methylation of its promoter region. Failure to methylate the *FWA* promoter results in an easily recognized late-flowering phenotype, allowing the isolation of *A. thaliana* mutants in multiple genes that fail to methylate CHH sequences. These genes have been cloned by methods described in Chapter 5, revealing a complex mechanism of RNA-directed DNA methylation that involves the plant-specific RNA polymerases IV and V mentioned earlier (Figure 7-51) and plant-specific nuclear siRNAs that are 24 nucleotides long.

The *FWA* gene has a direct duplication in its promoter region, and multiple copies of transposons are present in plant genomes. By a mechanism yet to be elucidated, Pol IV is directed to transcribe repeated DNA no matter what its sequence. An RNA-dependent RNA polymerase (RDR2) converts the single-stranded Pol IV transcript into double-stranded RNA, which is cleaved by Dicer ribonucleases, especially DCL3, into 24 nucleotide double-stranded fragments with two base overhangs. One strand of these RNA fragments

FIGURE 7-51 Model of the mechanism of DNA methylation at Cs in CHH sequences in *A. thaliana*. The plant-specific RNA polymerase IV transcribes repeated sequences such as transposons and the promoter-proximal region of the *FWA* gene (blue DNA, with the duplicated region indicated by blue arrows). The RNA-dependent RNA polymerase RDR2 converts this to double-stranded RNA, which is cleaved by the Dicer enzyme DCL3 into 24-nucleotide double-stranded RNA fragments with two base overhangs. One strand is bound by the Argonaute protein AGO4 or AGO6 and base-pairs with transcripts of repeated DNA transcribed by the plant-specific RNA polymerase V. This leads to methylation of Cs (M) by the DNA methyl transferase DRM2. Several other proteins that participate in this elaborate process are represented by colored circles. They were identified because mutations in them produce a late-flowering phenotype and they fail to methylate Cs in the *FWA* promoter region. [Adapted from M. V. C. Greenberg et al., 2011, *Epigenetics* 6:344.]

is bound by an Argonaute protein (AGO4 or 6) in dense bodies in the nucleus called Cajal bodies, after the Spanish biologist who first described them early in the twentieth century. The 24-nucleotide single-stranded RNA in these Argonaute complexes then base-pairs with a nascent transcript of repetitive DNA synthesized by Pol V. This directs the DRM2 DNA-methyl transferase to methylate Cs in the repeated DNA. As in metazoans, a histone deacetylase interacts with the methylated Cs, leading to hypoacetylation of nucleosomes associated with repeated DNA and repression of transcription by Pol II. ■

KEY CONCEPTS of Section 7.7

Epigenetic Regulation of Transcription

- The term *epigenetic* control of transcription refers to repression or activation that is maintained after cells replicate as the result of DNA methylation and/or post-translation modification of histones, especially histone methylation.
- Methylation of CpG sequences in CpG island promoters in mammals generates binding sites for a family of methyl-binding proteins (MBTs) that associate with histone deacetylases, inducing hypoacetylation of the promoter regions and transcriptional repression.

- Histone H3 lysine 9 di- and trimethylation creates binding sites for the heterochromatin-associated protein HP1, which results in the condensation of chromatin and transcriptional repression. These post-translational modifications are perpetuated following chromosome replication because the methylated histones are randomly associated with the daughter DNA molecules and associate with histone H3 lysine 9 methyl transferases that methylate histone 3 lysine 9 on newly synthesized histone H3 assembled on the daughter DNA.

- Polycomb complexes maintain repression of genes initially repressed by sequence-specific binding transcription factor repressors expressed early during embryogenesis. One class of Polycomb repression complexes, PRC2 complexes, is thought to associate with these repressors in early embryonic cells, resulting in methylation of histone H3 lysine 27. This creates binding sites for subunits in the PRC2 complex and PRC1-type complexes that inhibit the assembly of Pol II initiation complexes or inhibit transcription elongation. Since parental histone octamers with H3 methylated at lysine 27 are distributed to both daughter DNA molecules following DNA replication, PRC2 complexes that associate with these nucleosomes maintain histone H3 lysine 27 methylation through cell division.

- Trithorax complexes oppose repression by Polycomb complexes by methylating H3 at lysine 4 and maintaining this activating mark through chromosome replication.

- X-chromosome inactivation in female mammals requires a long noncoding RNA (ncRNA) called Xist that is transcribed from the X-inactivation center and then spreads by a poorly understood mechanism along the length of the same chromosome. Xist is bound by PRC2 complexes at an early stage of embryogenesis, initiating X inactivation that is maintained throughout the remainder of embryogenesis and adult life.

- Long ncRNAs also have been discovered that lead to repression of genes in *trans*, as opposed to the *cis* inactivation imposed by Xist. Repression is initiated by their interaction with PRC2 complexes. Much remains to be learned about how they are targeted to specific chromosomal regions, but the discovery of ~1600 long ncRNAs conserved between mammals raises the possibility that this is a widely utilized mechanism of repression.

- In many fungi and plants, RNA-dependent RNA polymerases generate double-stranded RNAs from nascent transcripts of repeated sequences. These double-stranded RNAs are processed by Dicer ribonucleases into 22- or 24-nucleotide siRNAs bound by Argonaute proteins. The siRNAs base-pair with nascent transcripts from the repeated DNA sequences, inducing histone H3 lysine 9 methylation at centromeric repeats in the fission yeast *S. pombe*, and DNA methylation in plants, resulting in the formation of transcriptionally repressed heterochromatin.

7.8 Other Eukaryotic Transcription Systems

We conclude this chapter with a brief discussion of transcription initiation by the other two eukaryotic nuclear RNA polymerases, Pol I and Pol III, and by the distinct polymerases that transcribe mitochondrial and chloroplast DNA. Although these systems, particularly their regulation, are less thoroughly understood than transcription by RNA polymerase II, they are equally as fundamental to the life of eukaryotic cells.

Transcription Initiation by Pol I and Pol III Is Analogous to That by Pol II

The formation of transcription-initiation complexes involving Pol I and Pol III is similar in some respects to assembly of Pol II initiation complexes (see Figure 7-17). However, each of the three eukaryotic nuclear RNA polymerases requires its own polymerase-specific general transcription factors and recognizes different DNA control elements. Moreover, neither Pol I nor Pol III requires ATP hydrolysis by a DNA helicase to help melt the DNA template strands to initiate transcription, whereas Pol II does. Transcription initiation by Pol I, which synthesizes pre-rRNA, and by Pol III, which synthesizes tRNAs, 5S rRNA, and other short, stable RNAs (see Table 7-2), is tightly coupled to the rate of cell growth and proliferation.

Initiation by Pol I The regulatory elements directing Pol I initiation are similarly located relative to the transcription start site in both yeast and mammals. A *core element* spanning the transcription start site from -40 to $+5$ is essential for Pol I transcription. An additional *upstream control element* extending from roughly -155 to -60 stimulates *in vitro* Pol I

transcription 10-fold. In humans, assembly of the Pol I pre-initiation complex (Figure 7-52) is initiated by the cooperative binding of UBF (upstream binding factor) and SL1 (selectivity factor), a multisubunit factor containing TBP and four Pol I-specific TBP-associated factors (TAF_Is) to the Pol I promoter region. The TAF_I subunits interact directly with Pol I-specific subunits, directing this specific nuclear RNA polymerase to the transcription start site. TIF-1A, the mammalian homolog of *S. cerevisiae* RRN3, is another required factor, as well as the abundant nuclear protein kinase CK2 (casein kinase 2), nuclear actin, nuclear myosin, the protein deacetylase SIRT7, and topoisomerase I, which prevents DNA supercoils (Figure 4-8) from forming during rapid Pol I transcription of the ≈ 14 -kb transcription unit.

Transcription of the ≈ 14 -kb precursor of 18S, 5.8S, and 28S rRNAs (see Chapter 8) is highly regulated to coordinate ribosome synthesis with cell growth and division. This is achieved through regulation of the activities of the Pol I initiation factors by post-translational modifications including phosphorylation and acetylation at specific sites, control of the rate of Pol I elongation, and control of the number of the ≈ 300 human rRNA genes that are transcriptionally active by epigenetic mechanisms that assemble inactive copies into heterochromatin. Switching between the active and heterochromatic silent copies of rRNA genes is accomplished by a multisubunit chromatin-remodeling complex called NoRC ("No" for nucleolus, the site of rRNA transcription within nuclei). NoRC localizes a nucleosome over the Pol I transcription start site, blocking preinitiation complex assembly. It also interacts with a DNA methyl transferase that methylates a critical CpG in the upstream control element, inhibiting binding by UBF, as well as histone methyltransferases

FIGURE 7-52 Transcription of the rRNA precursor RNA by RNA polymerase I. *Top:* electron micrograph of RNA protein complexes transcribed from repeated rRNA genes. One Pol I transcription unit is diagrammed in the middle. Enhancers that stimulate Pol I transcription from a single transcription start site are represented by blue boxes. Pol I transcription termination sites (T_0 , T_1 – T_{10}) bound by the Pol I-specific termination factor TTF-1 are shown as red rectangles. pRNA indicates

transcription of the noncoding pRNA required for transcriptional silencing. Regions of DNA shown in blue are contained in the primary transcript, but are removed and degraded during rRNA processing. The core promoter element and upstream control element are diagrammed below with the location of Pol I and its general transcription factors UBF, SL1, and TIF-1A represented, as well as other proteins required for Pol I elongation and control. [Adapted from I. Grummt, 2010, *FEBS J.* 277:4626.]

that di- and trimethylate histone H3 lysine 9, creating binding sites for heterochromatic HP1, and histone deacetylases. Moreover, an ≈ 250 -nucleotide noncoding RNA called pRNA (for promoter associated) transcribed by Pol I from ≈ 2 kb upstream of the rRNA transcription unit (red arrow in Figure 7-52) is bound by a subunit of NoRC and is required for transcriptional silencing. pRNA is believed to target NoRC to Pol I promoter regions by forming an RNA:DNA triplex with the T_0 terminator sequence. This creates a binding site for the DNA methyl transferase DNMT3b that methylates the critical CpG in the upstream promoter element.

Initiation by Pol III Unlike protein-coding genes and pre-rRNA genes, the promoter regions of tRNA and 5S-rRNA genes lie entirely within the transcribed sequence (Figure 7-53a, b). Two such *internal* promoter elements, termed the *A box* and the *B box*, are present in all tRNA genes. These highly conserved sequences not only function as promoters but also encode two invariant portions of eukaryotic tRNAs that are required for protein synthesis. In 5S-rRNA genes, a single internal control region, the *C box*, acts as a promoter.

Three general transcription factors are required for Pol III to initiate transcription of tRNA and 5S-rRNA genes *in vitro*. Two multimeric factors, TFIIB and TFIIC, participate in initiation at both tRNA and 5S-rRNA promoters; a third factor, TFIIA, is required for initiation at 5S-rRNA promoters. As with assembly of Pol I and Pol II initiation complexes, the Pol III general transcription factors bind to promoter DNA in a defined sequence.

The N-terminal half of one TFIIB subunit, called BRF (for TFIIB-related factor), is similar in sequence to TFIIB (a Pol II factor). This similarity suggests that BRF and TFIIB perform a similar function in initiation, namely, to assist in separating the template DNA strands at the transcription start site (Figure 7-19). Once TFIIB has bound to either a tRNA or 5S-rRNA gene, Pol III can bind and initiate transcription in the presence of ribonucleoside triphosphates. The BRF subunit of TFIIB interacts specifically with one of the polymerase subunits unique to Pol III, accounting for initiation by this specific nuclear RNA polymerase.

Another of the three subunits composing TFIIB is TBP, which we can now see is a component of a general transcription factor for all three eukaryotic nuclear RNA polymerases. The finding that TBP participates in transcription initiation by Pol I and Pol III was surprising, since the promoters recognized by these enzymes often do not contain TATA boxes. Nonetheless, in the case of Pol III transcription, the TBP subunit of TFIIB interacts with DNA similarly to the way it interacts with TATA boxes.

Pol III also transcribes genes for small, stable RNAs with upstream promoters containing a TATA box. One example is the U6 snRNA involved in pre-mRNA splicing, as discussed in Chapter 8. In mammals, this gene contains an upstream promoter element called the PSE in addition to the TATA box (Figure 7-53c), which is bound by a multisubunit complex called SNAPc, while the TATA box is bound by the TBP subunit of a specialized form of TFIIB containing an alternative BRF subunit.

MAF1 is a specific inhibitor of Pol III transcription that functions by interacting with the BRF subunit of TFIIB and Pol III. Its function is regulated by controlling its import from the cytoplasm into nuclei by phosphorylations at specific sites in response to signal transduction protein kinase cascades that respond to cell stress and nutrient deprivation (see Chapters 16 and 24). In mammals, Pol III transcription is also repressed by the critical tumor suppressors p53 and the retinoblastoma (RB) family. In humans there are two genes encoding subunit RPC32. One of these is expressed specifically in replicating cells, and its forced expression can contribute to oncogenic transformation of cultured human fibroblasts.

FIGURE 7-53 Transcription-control elements in genes transcribed by RNA polymerase III. Both tRNA (a) and 5S-rRNA (b) genes contain internal promoter elements (yellow) located downstream from the start site and named A, B, and C boxes, as indicated. Assembly of transcription initiation complexes on these genes begins with the binding of Pol III-specific general transcription factors TFIIB, TFIIC, and TFIIA to these control elements. Green arrows indicate interactions between general transcription factors. Blue arrows indicate strong, sequence-specific protein-DNA interactions. Purple arrows indicate interactions between general transcription factors and Pol III. (c) Transcription of the U6 snRNA gene in mammals is controlled by an upstream promoter with a TATA box bound by the TBP subunit of a specialized form of TFIIB with an alternative BRF subunit and an upstream regulatory element called the PSE bound by a multisubunit factor called SNAPc. [From L. Schramm and N. Hernandez, 2002, *Genes Dev.* 16:2593.]

Mitochondrial and Chloroplast DNAs Are Transcribed by Organelle-Specific RNA Polymerases

As discussed in Chapter 6, mitochondria and chloroplasts probably evolved from eubacteria that were endocytosed into ancestral cells containing a eukaryotic nucleus. In modern-day eukaryotes, both organelles contain distinct DNAs that encode some of the proteins essential to their specific functions. Interestingly, the RNA polymerases that transcribe mitochondrial (mt) DNA and chloroplast DNA are similar to polymerases from eubacteria and bacteriophages, reflecting their evolutionary origins.

Mitochondrial Transcription The RNA polymerase that transcribes mtDNA is encoded in nuclear DNA. After synthesis of the enzyme in the cytosol, it is imported into the mitochondrial matrix by mechanisms described in Chapter 13. The mitochondrial RNA polymerases from *S. cerevisiae* and the frog *Xenopus laevis* both consist of a large subunit with ribonucleotide-polymerizing activity and a small B subunit (TFBM). In mammals, another matrix protein, mitochondrial transcription factor A (TFAM), binds to mtDNA promoters and is essential for initiating transcription at the start sites used in the cell. The large subunit of yeast mitochondrial RNA polymerase clearly is related to the monomeric RNA polymerases of bacteriophage T7 and similar bacteriophages. However, the mitochondrial enzyme is functionally distinct from the bacteriophage enzyme in its dependence on two other polypeptides for transcription from the proper start sites.

The promoter sequences recognized by mitochondrial RNA polymerases include the transcription start site. These promoter sequences, which are rich in A residues, have been characterized in the mtDNA from yeast, plants, and animals. The circular human mitochondrial genome contains two related 15-bp promoter sequences, one for the transcription of each strand. Each strand is transcribed in its entirety; the long primary transcripts are then processed by cleavage at tRNA genes that separate each of the mitochondrial mRNAs and rRNAs. A second promoter appears to be responsible for transcribing additional copies of the rRNAs. Currently, there is relatively little understanding of how transcription of the mitochondrial genome is regulated to coordinate the production of the few mitochondrial proteins it encodes with synthesis and import of the thousands of nuclear DNA-encoded proteins that comprise the mitochondria.

Chloroplast Transcription Chloroplast DNA is transcribed by two types of RNA polymerases, one multisubunit protein similar to bacterial RNA polymerases and one similar to the single subunit enzymes of bacteriophages and mitochondria. The core subunits of the bacterial-type enzyme, α , β , β' , and ω subunits, are encoded in the chloroplast DNAs of higher plants, whereas six σ^{70} -like σ factors are encoded in the nuclear DNA of higher plants. This is another example of the transfer of genes from organellar genomes to nuclear genomes during evolution. In this case, genes encoding the

regulatory transcription initiation factors have been transferred to the nucleus, where the control of their transcription by nuclear RNA polymerase II likely indirectly controls the expression of sets of chloroplast genes. The bacterial-like chloroplast RNA polymerase is called the plastid polymerase because its catalytic core is encoded by the chloroplast genome. Most chloroplast genes are transcribed by these enzymes and have -35 and -10 control regions similar to promoters in cyanobacteria, from which they evolved. The chloroplast T7-like RNA polymerase is also encoded in the nuclear genome of higher plants. It transcribes a different set of chloroplast genes. Curiously, this includes genes encoding subunits of the bacterial-like multisubunit plastid polymerase. Recent results indicate that transcription by the multisubunit polymerase is regulated by sigma factors whose activities are regulated by light and metabolic stress.

KEY CONCEPTS of Section 7.8

Other Eukaryotic Transcription Systems

- The process of transcription initiation by Pol I and Pol III is similar to that by Pol II but requires different general transcription factors, is directed by different promoter elements, and does not require hydrolysis of ATP β - γ phosphodiester bonds to separate the DNA strands at the start site.
- Mitochondrial DNA is transcribed by a nuclear-encoded RNA polymerase composed of two subunits. One subunit is homologous to the monomeric RNA polymerase from bacteriophage T7; the other resembles bacterial σ factors.
- Chloroplast DNA is transcribed by a chloroplast-encoded RNA polymerase homologous to bacterial RNA polymerases, with several alternative nuclear encoded σ -factors, and a single subunit bacteriophage T7-like RNA polymerase.

Perspectives for the Future

A great deal has been learned in recent years about transcription control in eukaryotes. Genes encoding ≈ 2000 activators and repressors can be recognized in the human genome. We now have a glimpse of how the astronomical number of possible combinations of these transcription factors can generate the complexity of gene control required to produce organisms as remarkable as those we see around us. But very much remains to be understood. Although we now have some understanding of what processes turn a gene on and off, we have very little understanding of how the frequency of transcription is controlled in order to provide a cell with the appropriate amounts of its various proteins. In a red blood cell precursor, for example, the globin genes are transcribed at a far greater rate than the genes encoding the enzymes of intermediary metabolism (the so-called housekeeping genes). How are the vast differences in the frequency of transcription initiation at various genes achieved? What happens to the multiple interactions between activation domains,

co-activator complexes, general transcription factors, and RNA polymerase II when the polymerase initiates transcription and transcribes away from the promoter region? Do these completely dissociate at promoters that are transcribed infrequently, so that the combination of multiple factors required for transcription must be reassembled anew for each round of transcription? Do complexes of activators with their multiple interacting co-activators remain assembled at promoters from which reinitiation takes place at a high rate, so that the entire assembly does not have to be reconstructed each time a polymerase initiates?

Much remains to be learned about the structure of chromatin and how that structure influences transcription. What additional components besides HP1 and methylated histone H3 lysine 9 are required to direct certain regions of chromatin to form heterochromatin, where transcription is repressed? Precisely how is the structure of chromatin changed by activators and repressors, and how does this promote or inhibit transcription? Once chromatin-remodeling complexes and histone acetylase complexes become associated with a promoter region, how do they remain associated? Current models suggest that certain subunits of these complexes associate with modified histone tails so that the combination of binding to a specific histone tail modification plus modification of neighboring histone tails in the same way results in retention of the modifying complex at an activated promoter region. In some cases, this type of assembly mechanism causes the complexes to spread along the length of a chromatin fiber. What controls when such complexes spread and how far they will spread?

Single activation domains have been discovered to interact with several co-activator complexes. Are these interactions transient, so that the same activation domain can interact with several co-activators sequentially? Is a specific order of co-activator interaction required? How does the interaction of activation domains with mediator stimulate transcription? Do these interactions simply stimulate the assembly of a preinitiation complex, or do they also influence the rate at which RNA polymerase II initiates transcription from an assembled preinitiation complex?

Transcriptional activation is a highly cooperative process so that genes expressed in a specific type of cell are expressed only when the complete set of activators that control that gene are expressed and activated. As mentioned earlier, some of the transcription factors that control expression of the *TTR* gene in the liver are also expressed in intestinal and kidney cells. Yet the *TTR* gene is not expressed in these other tissues, since its transcription requires two additional transcription factors expressed only in the liver. What mechanisms account for this highly cooperative action of transcription factors that is critical to cell-type-specific gene expression?

The discovery that long noncoding RNAs can repress transcription of specific target genes has stimulated tremendous interest. Do these always repress transcription by targeting Polycomb complexes? Can long noncoding RNAs also activate transcription of specific target genes? How are they tar-

geted to specific genes? Do the ≈ 1600 long noncoding RNAs that are conserved between mammals all function to regulate transcription of specific target genes, adding to the complexity of transcription control by sequence-specific DNA-binding proteins? Research to address these questions will be an exciting area of investigation in the coming years.

A thorough understanding of normal development and of abnormal processes associated with disease will require answers to these and many related questions. As further understanding of the principles of transcription control are discovered, applications of the knowledge will likely be made. This understanding may allow fine control of the expression of therapeutic genes introduced by gene therapy vectors as they are developed. Detailed understanding of the molecular interactions that regulate transcription may provide new targets for the development of therapeutic drugs that inhibit or stimulate the expression of specific genes. A more complete understanding of the mechanisms of transcriptional control may allow improved engineering of crops with desirable characteristics. Certainly, further advances in the area of transcription control will help to satisfy our desire to understand how complex organisms such as ourselves develop and function.

Key Terms

activation domain 307	MAT locus (in yeast) 315
activators 281	mediator 315
antitermination factor 301	nuclear receptors 309
bromodomain 319	promoter 281
carboxyl-terminal domain (CTD) 293	promoter-proximal elements 302
chromatin-mediated repression 315	repression domain 308
chromodomain 330	repressors 281
co-activator 311	RNA polymerase II 290
co-repressor 312	silencer sequences 316
DNase I footprinting 305	specific transcription factors 305
enhanceosome 314	TATA box 295
enhancers 285	TATA box-binding protein (TBP) 298
general transcription factors 297	upstream activating sequences (UASs) 305
heat-shock genes 325	yeast two-hybrid system 321
histone deacetylation 318	zinc finger 309
leucine zipper 311	

Review the Concepts

1. Describe the molecular events that occur at the *lac* operon when *E. coli* cells are shifted from a glucose-containing medium to a lactose-containing medium.
2. The concentration of free glutamine affects transcription of the enzyme glutamine synthetase in *E. coli*. Describe the mechanism for this.

3. What types of genes are transcribed by RNA polymerases I, II, and III? Design an experiment to determine whether a specific gene is transcribed by RNA polymerase II.
4. The CTD of the largest subunit of RNA polymerase II can be phosphorylated at multiple serine residues. What are the conditions that lead to the phosphorylated versus unphosphorylated RNA polymerase II CTD?
5. What do TATA boxes, initiators, and CpG islands have in common? Which was the first of these to be identified? Why?
6. Describe the methods used to identify the location of DNA-control elements in promoter-proximal regions of genes.
7. What is the difference between a promoter-proximal element and a distal enhancer? What are the similarities?
8. Describe the methods used to identify the location of DNA-binding proteins in the regulatory regions of genes.
9. Describe the structural features of transcriptional activator and repressor proteins.
10. Give two examples of how gene expression may be repressed without altering the gene-coding sequence.
11. Using CREB and nuclear receptors as examples, compare and contrast the structural changes that take place when these transcription factors bind to their co-activators.
12. What general transcription factors associate with an RNA polymerase II promoter in addition to the polymerase? In what order do they bind *in vitro*? What structural change occurs in the DNA when an "open" transcription-initiation complex is formed?
13. Expression of recombinant proteins in yeast is an important tool for biotechnology companies that produce new drugs for human use. In an attempt to get a new gene *X* expressed in yeast, a researcher has integrated gene *X* into the yeast genome near a telomere. Will this strategy result in good expression of gene *X*? Why or why not? Would the outcome of this experiment differ if the experiment had been performed in a yeast line containing mutations in the H3 or H4 histone tails?
14. You have isolated a new protein called STICKY. You can predict from comparisons with other known proteins that STICKY contains a bHLH domain and a Sin3-interacting domain. Predict the function of STICKY and rationale for the importance of these domains in STICKY function.
15. The yeast two-hybrid method is a powerful molecular genetic method to identify a protein(s) that interacts with a known protein or protein domain. You have isolated the glucocorticoid receptor (GR) and have evidence that it is a modular protein containing an activation domain, a DNA-binding domain, and a second ligand-binding activation domain. Further analysis reveals that in pituitary cells, the protein is anchored in the cytoplasm in the absence of its hormone ligand, a result leading you to speculate that it binds to other inhibitory proteins. Describe how a two-hybrid analysis could be used to identify the protein(s) with which GR interacts. How would you specifically identify the domain in the GR that binds the inhibitor(s)?
16. Prokaryotes and lower eukaryotes such as yeast have DNA-regulatory elements called upstream activating

sequences. What are the comparable sequences found in higher eukaryotic species?

17. Recall that the Trp repressor binds to a site in the operator region of tryptophan-producing genes when tryptophan is abundant, thereby preventing transcription. What would happen to the expression of the tryptophan biosynthetic enzyme genes in the following scenarios? Fill in the blanks with one of the following phrases:

never be expressed/always (constitutively) be expressed

- a. The cell produces a mutant Trp repressor that cannot bind to the operator. The enzyme genes will _____.
 - b. The cell produces a mutant Trp repressor that binds to its operator site even if no Tryptophan is present. The enzyme genes will _____.
 - c. The cell produces a mutant sigma factor that cannot bind the promoter region. The enzyme genes will _____.
 - d. Elongation of the leader sequence is always stalled after transcription of region 1. The enzyme genes will _____.
18. Compare/contrast bacterial and eukaryotic gene expression mechanisms.
 19. You are curious to identify the region of gene *X* sequence that serves as an enhancer for gene expression. Design an experiment to investigate this issue.
 20. Some organisms have mechanisms in place that will override transcription termination. One such mechanism using the Tat protein is employed by the HIV retrovirus. Explain why Tat is therefore a good target for HIV vaccination.
 21. Upon identification of the DNA regulatory sequence responsible for translating a given gene, you note that it is enriched with CG sequences. Is the corresponding gene likely to be a highly expressed transcript?
 22. Name four major classes of DNA-binding proteins that are responsible for controlling transcription, and describe their structural features.

Analyze the Data

In eukaryotes, the three RNA polymerases, Pol I, II, and III, each transcribes unique genes required for the synthesis of ribosomes: 25S and 18S rRNAs (Pol I), 5S rRNA (Pol III), and mRNAs for ribosomal proteins (Pol II). Researchers have long speculated that the activities of the three RNA polymerases are coordinately regulated according to the demand for ribosome synthesis: high in replicating cells in rich nutrient conditions and low when nutrients are scarce. To determine whether the activities of the three polymerases are coordinated, Laferte and colleagues engineered a strain of yeast to be partially resistant to the inhibition of cell growth by the drug rapamycin (2006, *Genes Dev.* 20:2030–2040). As discussed in Chapter 8, rapamycin inhibits a protein kinase (called TOR, for target of rapamycin) that regulates the overall rate of protein synthesis and ribosome synthesis. When TOR is inhibited by rapamycin, the transcription of rRNAs by Pol I and Pol III and ribosomal protein mRNAs

by RNA polymerase II are all rapidly repressed. Part of the inhibition of Pol I rRNA synthesis results from the dissociation of the Pol I transcription factor Rrn3 from Pol I. In the strain constructed by Laferte and colleagues, the wild-type *Rrn3* gene and the wild-type *A43* gene, encoding the Pol I subunit to which Rrn3 binds, were replaced with a gene encoding a fusion protein of the A43 Pol I subunit with Rrn3. The idea was that the covalent fusion of the two proteins would prevent the Rrn3 dissociation from Pol I otherwise caused by rapamycin treatment. The resulting CARA (constitutive association of Rrn3 and A43) strain was found to be partially resistant to rapamycin. In the absence of rapamycin, the CARA strain grew at the same rate and had equal numbers of ribosomes as wild-type cells.

a. To analyze rRNA transcription by Pol I, total RNA was isolated from rapidly growing wild-type (WT) and CARA cells at various times following the addition of rapamycin. The concentration of the 35S rRNA precursor transcribed by Pol I (see Figure 8-38) was assayed by the primer-extension method. Since the 5' end of the 35S rRNA precursor is degraded during the processing of 25S and 18S rRNA, this method measures the relatively short-lived pre-rRNA precursor. This is an indirect measure of the rate of rRNA transcription by Pol I. The results of this primer extension assay are shown below. How does the CARA Pol I-Rrn3 fusion affect the response of Pol I transcription to rapamycin?

b. The concentrations of four mRNAs encoding ribosomal proteins, RPL30, RPS6a, RPL7a, and RPL5, and the mRNA for actin (*ACT1*), a protein present in the cytoskeleton, were assessed in wild-type and CARA cells by Northern blotting at various times after addition of rapamycin to rapidly growing cells (upper autoradiograms). 5S rRNA transcription was assayed by pulse labeling rapidly growing WT

and CARA cells with ^3H uracil (for 20 minutes) at various times after addition of rapamycin to the media. Total cellular RNA was isolated and subjected to gel electrophoresis and autoradiography. The lower autoradiogram shows the region of the gel containing 5S rRNA. Based on these data, what can be concluded about the influence of Pol I transcription on the transcription of ribosomal protein genes by Pol II and 5S rRNA by Pol III?

c. To determine whether the difference in behavior of wild-type and CARA cells can be observed under normal physiological conditions (i.e., without drug treatment), cells were subjected to a shift in their food source, from nutrient-rich media to nutrient-poor media. Under these conditions, in wild-type cells, the TOR protein kinase becomes inactive. Consequently, shifting cells from nutrient-rich media to nutrient-poor media should result in a normal physiological response that is equivalent to treating cells with rapamycin, which inhibits TOR. To determine how the CARA fusion protein affected the response to this media shift, RNA was extracted from wild-type and CARA cells and used to probe microarrays containing all yeast open reading frames. The extent of RNA hybridization with the arrays was quantified and is expressed in the graphs as $\log_2$ of the ratio of CARA-cell RNA concentration to wild-type-cell RNA concentration for each open reading frame. A value of zero indicates that the two strains of yeast exhibit the same level of expression for those specific RNAs. A value of 1 indicates that the CARA cells contain twice as much of that particular RNA as do wild-type cells. The graphs below show the number of open reading frames (y axis) that have values for $\log_2$ of this ratio, indicated by the x axis. The results of hybridization to open reading frames encoding mRNAs for ribosomal proteins are shown by black bars, those for all other mRNAs by white bars. The graph on the left gives results for cells grown in nutrient-rich medium, the graph on the right for cells shifted to nutrient-poor medium for 90 minutes. What do these data suggest about the regulation of ribosomal protein gene transcription by Pol II?

Post-transcriptional Gene Control

In the previous chapter, we saw that most genes are regulated at the first step in gene expression, transcription, by regulating the assembly of the transcription pre-initiation complex on a promoter DNA sequence and regulating transcription elongation in the promoter proximal region. Once transcription has been initiated, synthesis of the encoded RNA requires that RNA polymerase transcribe the entire gene and not terminate prematurely. Moreover, the initial **primary transcripts** produced from eukaryotic genes must undergo various processing reactions to yield the corresponding functional RNAs. For mRNAs, the 5' cap structure necessary for translation must be added (see Figure 4-14), introns must be spliced out of pre-mRNAs (Table 8-1), and the 3' end must be polyadenylated (see Figure 4-15). Once formed in the nucleus, mature, functional RNAs are exported to the cytoplasm as components of ribonucleoproteins. Both processing of RNAs and their export from the nucleus offer opportunities for further regulating gene expression after the initiation of transcription.

Recently, the vast amount of sequence data on human mRNAs expressed in different tissues and at various times during embryogenesis and cellular differentiation has revealed

that ~95 percent of human genes give rise to alternatively spliced mRNAs. These alternatively spliced mRNAs encode related proteins with differences in sequences limited to specific functional domains. In many cases, alternative RNA splicing is regulated to meet the need for a specific protein isoform in a specific cell type. Given the complexity of pre-mRNA splicing, it is not surprising that mistakes are occasionally made, giving rise to mRNA precursors with improperly spliced exons. However, eukaryotic cells have evolved RNA surveillance mechanisms that prevent the transport of incorrectly processed RNAs to the cytoplasm or lead to their degradation if they are transported.

Additional control of gene expression can occur in the cytoplasm. In the case of protein-coding genes, for instance, the amount of protein produced depends on the stability of the corresponding mRNAs in the cytoplasm and the rate of their translation. For example, during an immune response, lymphocytes communicate by secreting polypeptide hormones called cytokines that signal neighboring lymphocytes through cytokine receptors that span their plasma membranes (Chapter 23). It is important for lymphocytes to synthesize and secrete cytokines in short bursts. This is possible

TABLE 8-1 RNAs Discussed in Chapter 8

mRNA	Fully processed messenger RNA with 5' cap, introns removed by RNA splicing, and a poly(A) tail
pre-mRNA	An mRNA precursor containing introns and not cleaved at the poly(A) site
hnRNA	Heterogeneous nuclear RNAs. These include pre-mRNAs and RNA processing intermediates containing one or more introns.
snRNA	Five small nuclear RNAs that function in the removal of introns from pre-mRNAs by RNA splicing, plus two small nuclear RNAs that substitute for the first two at rare introns
pre-tRNA	A tRNA precursor containing additional transcribed bases at the 5' and 3' ends compared to the mature tRNA. Some pre-tRNAs also contain an intron in the anti-codon loop.
pre-rRNA	The precursor to mature 18S, 5.8S, and 28S ribosomal RNAs. The mature rRNAs are processed from this long precursor RNA molecule by cleavage, removal of bases from the ends of the cleaved products, and modification of specific bases.
snoRNA	Small nucleolar RNAs. These base-pair with complementary regions of the pre-RNA molecule, directing cleavage of the RNA chain and modification of bases during maturation of the rRNAs.
siRNA	Short interfering RNAs, ~22 bases long, that are each perfectly complementary to a sequence in an mRNA. Together with associated proteins, siRNAs cause cleavage of the "target" RNA, leading to its rapid degradation.
miRNA	Micro RNAs, ~22 bases long, that base-pair extensively, but not completely, with mRNAs, especially over the six base pairs at the 5' end of the miRNA. This inhibits translation of the "target" mRNA.

because cytokine mRNAs are extremely unstable. Consequently, the concentration of the mRNA in the cytoplasm falls rapidly once its synthesis is stopped. In contrast, mRNAs encoding proteins required in large amounts that function over long periods, such as ribosomal proteins, are extremely stable so that multiple polypeptides are transcribed from each mRNA.

In addition to regulation of pre-mRNA processing, nuclear export, and translation, the cellular locations of many, if not most, mRNAs are regulated so that newly synthesized protein is concentrated where it is needed. Particularly striking examples of this occur in the nervous systems of multicellular animals. Some neurons in the human brain generate more than 1000 separate synapses with other neurons. During the process of learning, synapses that fire more frequently than others increase in size many times, while other synapses made by the same neuron do not. This can occur because mRNAs encoding proteins critical for synapse enlargement are stored at all synapses, but translation of these localized, stored mRNAs is regulated at each synapse independently by the frequency at which it initiates firing. In this way, synthesis of synapse-associated proteins can be regulated independently at each of the many synapses made by the same neuron.

Another type of gene regulation that has recently come to light involves micro RNAs (miRNAs), which regulate the stability and translation of specific target mRNAs in multicellular animals and plants. Analyses of these short miRNAs in various human tissues indicate that there are ~500 miRNAs

expressed in the multiple types of human cells. Although some have recently been discovered to function through inhibition of target gene expression in the appropriate tissue and at the appropriate time in development, the functions of the vast majority of human miRNAs are unknown and are the subject of a growing new area of research. If most miRNAs do indeed have significant functions, miRNA genes constitute an important subset of the ~25,000 human genes. A closely related process called RNA interference (RNAi) leads to the degradation of viral RNAs in infected cells and the degradation of transposon-encoded RNAs in many eukaryotes. This is of tremendous significance to biological researchers because it is possible to design **short interfering RNAs (siRNA)** to inhibit the translation of specific mRNAs experimentally by a process called *RNA knockdown*. This makes it possible to inhibit the function of any desired gene, even in organisms that are not amenable to classic genetic methods for isolating mutants.

We refer to all the mechanisms that regulate gene expression following transcription as *post-transcriptional gene control* (Figure 8-1). Since the stability and translation rate of an mRNA contribute to the amount of protein expressed from a gene, these post-transcriptional processes are important components of **gene control**. Indeed, the protein output of a gene is regulated at every step in the life of an mRNA from the initiation of its synthesis to its degradation. Thus genetic regulatory processes act on RNA as well as DNA. In this chapter, we consider the events that occur in the processing of mRNA following transcription initiation and promoter proximal

FIGURE 8-1 Overview of RNA processing and post-transcriptional gene control. Nearly all cytoplasmic RNAs are processed from primary transcripts in the nucleus before they are exported to the cytoplasm. For protein-coding genes transcribed by RNA polymerase II, gene control can be exerted through **1** the choice of alternative exons during pre-mRNA splicing and **2** the choice of alternative poly(A) sites. Improperly processed mRNAs are blocked from export to the cytoplasm and degraded **3** by a large complex called the exosome that contains multiple ribonucleases. Once exported to the cytoplasm, **4** translation initiation factors bind to the mRNA 5'-cap cooperatively with poly(A)-binding protein I bound to the poly(A) tail and initiate translation (see Figure 4-28). **5** mRNA is degraded in the cytoplasm by de-adenylation and decapping followed

by degradation by cytoplasmic exosomes. The degradation rate of each mRNA is controlled, thereby regulating the mRNA concentration and, consequently, the amount of protein translated. Some mRNAs are synthesized without long poly(A) tails. Their translation is regulated by **6** controlling the synthesis of a long poly(A) tail by a cytoplasmic poly(A) polymerase. **7** Translation is also regulated by other mechanisms including miRNAs. When expressed, these ~22-nucleotide RNAs inhibit translation of mRNAs to which they hybridize, usually in the 3'-untranslated region. tRNAs and rRNAs are also synthesized as precursor RNAs that must be **8** processed before they are functional. Regions of precursors cleaved from the mature RNAs are degraded by nuclear exosomes **9**. [Adapted from Houseley, et. al., 2006, *Nat. Rev. Mol. Cell Biol.* 7:529.]

elongation and the various mechanisms that are known to regulate these events. In the last section, we briefly discuss the processing of primary transcripts produced from genes encoding rRNAs and tRNAs.

8.1 Processing of Eukaryotic Pre-mRNA

In this section, we take a closer look at how eukaryotic cells convert the initial primary transcript synthesized by RNA polymerase II into a functional mRNA. Three major events occur during the process: *5' capping*, *3' cleavage/polyadenylation*, and *RNA splicing* (Figure 8-2). Adding these specific modifications to the 5' and 3' ends of the pre-mRNA is important to protect it from enzymes that quickly digest uncapped RNAs generated by RNA processing, such as spliced-out introns and RNA transcribed downstream from a polyadenylation site. The 5' cap and 3' poly(A) tail distinguish pre-mRNA molecules from the many other kinds of RNAs in the nucleus. Pre-mRNA molecules (see Table 8-1) are bound by nuclear proteins that function in mRNA export to the cytoplasm. After mRNAs are exported to the cytoplasm, they are bound by a set of cytoplasmic proteins that stimulate translation and are critical for mRNA stability in the cytoplasm. Prior to nuclear export, introns must be removed to generate the correct coding region of the mRNA. In higher eukaryotes, including humans, alternative splicing is intricately regulated in order to substitute different functional domains into proteins, producing a considerable expansion of the proteome of these organisms.

The pre-mRNA processing events of capping, splicing, and polyadenylation occur in the nucleus as the nascent mRNA

precursor is being transcribed. Thus pre-mRNA processing is *co-transcriptional*. As the RNA emerges from the surface of RNA polymerase II, its 5' end is immediately modified by the addition of the 5' cap structure found on all mRNAs (see Figure 4-14). As the nascent pre-mRNA continues to emerge from the surface of the polymerase, it is immediately bound by members of a complex group of RNA-binding proteins that assist in RNA splicing and export of the fully processed mRNA through nuclear pore complexes into the cytoplasm. Some of these proteins remain associated with the mRNA in the cytoplasm, but most either remain in the nucleus or shuttle back into the nucleus shortly after the mRNA is exported to the cytoplasm. Cytoplasmic RNA-binding proteins are exchanged for the nuclear ones. Consequently, mRNAs never occur as free RNA molecules in the cell but are always associated with protein as **ribonucleoprotein (RNP) complexes**, first as nascent *pre-mRNPs* that are capped and spliced as they are transcribed. Then, following cleavage and polyadenylation, they are referred to as *nuclear mRNPs*. Following the exchange of proteins that accompany export to the cytoplasm, they are called *cytoplasmic mRNPs*. Although we frequently refer to pre-mRNAs and mRNAs, it is important to remember that they are always associated with proteins as RNP complexes.

The 5' Cap Is Added to Nascent RNAs Shortly After Transcription Initiation

As the nascent RNA transcript emerges from the RNA channel of RNA polymerase II and reaches a length of ~25 nucleotides, a protective cap composed of 7-methylguanosine and methylated riboses is added to the 5' end of eukaryotic

ANIMATION: Life Cycle of an mRNA

FIGURE 8-2 Overview of mRNA processing in eukaryotes. Shortly after RNA polymerase II initiates transcription at the first nucleotide of the first exon of a gene, the 5' end of the nascent RNA is capped with 7-methylguanylate (step 1). Transcription by RNA polymerase II terminates at any one of multiple termination sites downstream from the poly(A) site, which is located at the 3' end of the final exon. After the primary transcript is cleaved at the poly(A) site (step 2), a string of

adenosine (A) residues is added (step 3). The poly(A) tail contains ~250 A residues in mammals, ~150 in insects, and ~100 in yeasts. For short primary transcripts with few introns, splicing (step 4) usually follows cleavage and polyadenylation, as shown. For large genes with multiple introns, introns often are spliced out of the nascent RNA during its transcription, i.e., before transcription of the gene is complete. Note that the 5' cap and sequence adjacent to the poly(A) tail are retained in mature mRNAs.

FIGURE 8-3 Synthesis of 5'-cap on eukaryotic mRNAs. The 5' end of a nascent RNA contains a 5'-triphosphate from the initiating NTP. The γ -phosphate is removed in the first step of capping, while the remaining α - and β -phosphates (orange) remain associated with the cap. The third phosphate of the 5',5'-triphosphate bond is derived from the α -phosphate of the GTP that donates the guanine. The methyl donor for methylation of the cap guanine and the first one or two riboses of the mRNA is S-adenosylmethionine (S-Ado-Met). [From S. Venkatesan and B. Moss, 1982, *Proc. Natl. Acad. Sci. USA* 79:304.]

mRNAs (see Figure 4-14). The 5' *cap* marks RNA molecules as mRNA precursors and protects them from RNA-digesting enzymes (5'-exoribonucleases) in the nucleus and cytoplasm. This initial step in RNA processing is catalyzed by a dimeric capping enzyme, which associates with the phosphorylated carboxyl-terminal domain (CTD) of RNA polymerase II. Recall that the CTD becomes phosphorylated by the TFIIF general transcription factor at multiple serines at the 5 position in the CTD heptapeptide repeat during transcription initiation (see Figure 7-17). Binding to the phosphorylated CTD stimulates the activity of the capping enzymes so that they are focused on RNAs containing a 5'-triphosphate that emerge from RNA polymerase II and not on RNAs transcribed by RNA polymerases I or III, which do not have a CTD. This is important because pre-mRNA synthesis accounts for only ~80 percent of the total RNA synthesized in replicating cells. About 20 percent is preribosomal RNA, which is transcribed by RNA polymerase I, and 5S rRNA, tRNAs, and other stable small RNAs, which are transcribed by RNA polymerase III. The two mechanisms of (1) binding of the capping enzyme to initiated RNA polymerase II specifically through its unique, phosphorylated CTD and (2)

activation of the capping enzyme by the phosphorylated CTD result in specific capping of RNAs transcribed by RNA polymerase II.

One subunit of the capping enzyme removes the γ -phosphate from the 5' end of the nascent RNA (Figure 8-3). Another domain of this subunit transfers the GMP moiety from GTP to the 5'-diphosphate of the nascent transcript, creating the unusual guanosine 5'-5'-triphosphate structure. In the final steps, separate enzymes transfer methyl groups from S-adenosylmethionine to the N₇ position of the guanine and one or two 2' oxygens of riboses at the 5' end of the nascent RNA.

Considerable evidence indicates that capping of the nascent transcript is coupled to elongation by RNA polymerase II so that all of its transcripts are capped during the earliest phase of elongation. As discussed in Chapter 7, in metazoans, during the initial phase of transcription the polymerase elongates the nascent transcript very slowly due to association of NELF (*negative elongation factor*) with RNA polymerase II in the promoter proximal region (see Figure 7-20). Once the 5' end of the nascent RNA is capped, phosphorylation of the RNA polymerase CTD at position 2 in the heptapeptide repeat and of NELF and DSIF by the CDK9-cyclin T protein kinase causes the release of NELF. This allows RNA polymerase II to enter into a faster mode of elongation that rapidly transcribes away from the promoter. The net effect of this mechanism is that the polymerase waits for the nascent RNA to be capped before elongating at a rapid rate.

A Diverse Set of Proteins with Conserved RNA-Binding Domains Associate with Pre-mRNAs

As noted earlier, neither nascent RNA transcripts from protein-coding genes nor the intermediates of mRNA processing, collectively referred to as **pre-mRNA**, exist as free RNA molecules in the nuclei of eukaryotic cells. From the time nascent transcripts first emerge from RNA polymerase II until mature mRNAs are transported into the cytoplasm, the RNA molecules are associated with an abundant set of nuclear proteins. These are the major protein components of *heterogeneous ribonucleoprotein particles* (*hnRNPs*), which contain *heterogeneous nuclear RNA* (*hnRNA*), a collective term referring to pre-mRNA and other nuclear RNAs of various sizes. These hnRNP proteins contribute to further steps in RNA processing, including splicing, polyadenylation, and export through nuclear pore complexes to the cytoplasm.

Researchers identified hnRNP proteins by first exposing cultured cells to high-dose UV irradiation, which causes covalent cross-links to form between RNA bases and closely associated proteins. Chromatography of nuclear extracts from treated cells on an oligo-dT cellulose column, which binds RNAs with a poly(A) tail, was used to recover the proteins that had become cross-linked to nuclear polyadenylated RNA. Subsequent treatment of cell extracts from un-irradiated cells with monoclonal antibodies specific for the major proteins identified by this

FIGURE 8-4 Human hnRNP A1 protein can cycle in and out of the cytoplasm, but human hnRNP C protein cannot. Cultured HeLa cells and *Xenopus* cells were fused by treatment with polyethylene glycol, producing heterokaryons containing nuclei from each cell type. The hybrid cells were treated with cycloheximide immediately after fusion to prevent protein synthesis. After 2 hours, the cells were fixed and stained with fluorescent-labeled antibodies specific for human hnRNP C and A1 proteins. These antibodies do not bind to the homologous *Xenopus* proteins. (a) A fixed preparation viewed by phase-contrast microscopy includes unfused HeLa cells (arrowhead) and *Xenopus* cells (dotted arrow), as well as fused heterokaryons (solid arrow). In the heterokaryon in this micrograph, the round HeLa-cell nucleus is to the

right of the oval-shaped *Xenopus* nucleus. (b, c) When the same preparation was viewed by fluorescence microscopy, the stained hnRNP C protein appeared green and the stained hnRNP A1 protein appeared red. Note that the unfused *Xenopus* cell on the left is unstained, confirming that the antibodies are specific for the human proteins. In the heterokaryon, hnRNP C protein appears only in the HeLa-cell nucleus (b), whereas the A1 protein appears in both the HeLa-cell nucleus and the *Xenopus* nucleus (c). Since protein synthesis was blocked after cell fusion, some of the human hnRNP A1 protein must have left the HeLa-cell nucleus, moved through the cytoplasm, and entered the *Xenopus* nucleus in the heterokaryon. [See S. Pinol-Roma and G. Dreyfuss, 1992, *Nature* **355**:730; courtesy of G. Dreyfuss.]

cross-linking technique revealed a complex set of abundant hnRNP proteins ranging in size from ~30 to ~120 kDa.

Like transcription factors, most hnRNP proteins have a modular structure. They contain one or more *RNA-binding domains* and at least one other domain that interacts with other proteins. Several different RNA-binding motifs have been identified by creating hnRNP proteins with missing amino acid sequences and testing their ability to bind RNA.

Functions of hnRNP Proteins The association of pre-mRNAs with hnRNP proteins prevents the pre-mRNAs from forming short secondary structures dependent on base pairing of complementary regions, thereby making the pre-mRNAs accessible for interaction with other RNA molecules or proteins. Pre-mRNAs associated with hnRNP proteins present a more uniform substrate for subsequent processing steps than would free, unbound pre-mRNAs, in which each mRNA forms a unique secondary structure due to its specific sequence.

Binding studies with purified hnRNP proteins indicate that different hnRNP proteins associate with different regions of a newly made pre-mRNA molecule. For example, the hnRNP proteins A1, C, and D bind preferentially to the pyrimidine-rich sequences at the 3' ends of introns (see Figure 8-7). Some hnRNP proteins interact with the RNA sequences that specify RNA splicing or cleavage/polyadenylation and contribute to the structure recognized by RNA-processing factors. Finally, cell-fusion experiments have shown that some hnRNP proteins remain localized in the nucleus, whereas others cycle in and

out of the cytoplasm, suggesting that they function in the transport of mRNA (Figure 8-4).

Conserved RNA-Binding Motifs The *RNA recognition motif* (RRM), also called the RNP motif and the RNA-binding domain (RBD), is the most common RNA-binding domain in hnRNP proteins. This ~80-residue domain, which occurs in many other RNA-binding proteins, contains two highly conserved sequences (RNP1 and RNP2) that are found across organisms ranging from yeast to human—indicating that like many DNA-binding domains, they evolved early in eukaryotic evolution.

Structural analyses have shown that the RRM domain consists of a four-stranded β sheet flanked on one side by two α helices. To interact with the negatively charged RNA phosphates, the β sheet forms a positively charged surface. The conserved RNP1 and RNP2 sequences lie side by side on the two central β strands, and their side chains make multiple contacts with a single-stranded region of RNA that lies across the surface of the β sheet (Figure 8-5).

The 45-residue *KH motif* is found in the hnRNP K protein and several other RNA-binding proteins. The three-dimensional structure of representative KH domains is similar to that of the RRM domain but smaller, consisting of a three-stranded β sheet supported from one side by two α helices. Nonetheless, the KH domain interacts with RNA much differently than does the RRM domain. RNA binds to the KH domain by interacting with a hydrophobic surface

(a) RNA recognition motif (RRM)

(b) Sex-lethal (Sxl) RRM domains

(c) Polypyrimidine tract binding protein (PTB)

FIGURE 8-5 Structure of the RRM domain and its interaction with RNA. (a) Diagram of the RRM domain showing the two α helices (green) and four β strands (red) that characterize this motif. The conserved RNP1 and RNP2 regions are located in the two central β strands. (b) Surface representation of the two RRM domains in *Drosophila* Sex-lethal (Sxl) protein, which bind a nine-base sequence in transformer pre-mRNA (yellow). The two RRMs are oriented like the two parts of an open pair of castanets, with the β sheet of RRM1 facing upward and the β sheet of RRM2 facing downward. Positively charged regions in Sxl protein are shown in shades of blue; negatively charged

regions, in shades of red. The pre-mRNA is bound to the surfaces of the positively charged β sheets, making most of its contacts with the RNP1 and RNP2 regions of each RRM. (c) Strikingly different orientation of RRM domains in a different hnRNP, the polypyrimidine tract binding (PTB) protein, illustrating that RRMs are oriented in different relative positions in different hnRNPs; colors are as in (b). Polypyrimidine (p(Y)) single-stranded RNA is bound to the upward (RRM3) and downward (RRM4) facing β -sheets. RNA is shown in yellow. (Part (a) adapted from K. Nagai et al., 1995, *Trends Biochem. Sci.* **20**:235. Part (b) after N. Harada et al., 1999, *Nature* **398**:579. Part (c) after F. C. Oberstrass et al., 2006, *Science* **309**:2054.)

formed by the α helices and one β strand. The *RGG box*, another RNA-binding motif found in hnRNP proteins, contains five Arg-Gly-Gly (RGG) repeats with several interspersed aromatic amino acids. Although the structure of this motif has not yet been determined, its arginine-rich nature is similar to the RNA-binding domains of the HIV Tat protein. KH domains and RGG repeats are often interspersed in two or more sets in a single RNA-binding protein.

Splicing Occurs at Short, Conserved Sequences in Pre-mRNAs via Two Transesterification Reactions

During formation of a mature, functional mRNA, the introns are removed and exons are spliced together. For short transcription units, RNA splicing usually follows cleavage and polyadenylation of the 3' end of the primary transcript, as depicted in Figure 8-2. However, for long transcription units containing multiple exons, splicing of exons in the nascent RNA begins before transcription of the gene is complete.

Early pioneering research on the nuclear processing of mRNAs revealed that mRNAs are initially transcribed as much longer RNA molecules than the mature mRNAs in the cytoplasm. It was also shown that RNA sequences near the 5' cap added shortly after transcription initiation are retained in the mature mRNA, and that RNA sequences near

the polyadenylated end of mRNA processing intermediates in hnRNA are retained in the mature mRNA in the cytoplasm. The solution to this apparent conundrum came from the discovery of introns by electron microscopy of RNA-DNA hybrids of adenovirus DNA and the mRNA encoding hexon, a major virion capsid protein (Figure 8-6). Other studies revealed nuclear viral RNAs that were colinear with the viral DNA (primary transcripts), and RNAs with one or two of the introns removed (processing intermediates). These results, together with the earlier findings that the 5' cap and 3' poly(A) tail at each end of long mRNA precursors are retained in shorter mature cytoplasmic mRNAs, led to the realization that introns are removed from primary transcripts as exons are spliced together.

The location of *splice sites*—that is, exon-intron junctions—in a pre-mRNA can be determined by comparing the sequence of genomic DNA with that of the cDNA prepared from the corresponding mRNA (see Figure 5-15). Sequences that are present in the genomic DNA but absent from the cDNA represent introns and indicate the positions of splice sites. Such analysis of a large number of different mRNAs revealed moderately conserved, short consensus sequences at the splice sites flanking introns in eukaryotic pre-mRNAs; a pyrimidine-rich region just upstream of the 3' splice site also is common (Figure 8-7). Studies of mutant genes with deletions introduced into introns have shown that much of the

EXPERIMENTAL FIGURE 8-6 Electron microscopy of mRNA-template DNA hybrids shows that introns are spliced out during pre-mRNA processing.

(a) Diagram of the *EcoRI* A fragment of adenovirus DNA, which extends from the left end of the genome to just before the end of the final exon of the hexon gene. The gene consists of three short exons and one long (~3.5 kb) exon separated by three introns of ~1, 2.5, and 9 kb. (b) Electron micrograph (left) and schematic drawing (right) of a hybrid between an *EcoRI* A DNA fragment and a hexon mRNA. The loops marked A, B, and C correspond to the introns indicated in (a). Since these intron sequences in the viral genomic DNA are not present in the mature hexon mRNA, they loop out between the exon sequences that hybridize to their complementary sequences in the mRNA. [Micrograph from S. M. Berget et al., 1977, *Proc. Nat'l. Acad. Sci. USA* 74:3171; courtesy of P. A. Sharp.]

center portion of introns can be removed without affecting splicing; generally only 30–40 nucleotides at each end of an intron are necessary for splicing to occur at normal rates.

Analysis of the intermediates formed during splicing of pre-mRNAs in vitro led to the discovery that splicing of exons proceeds via two sequential *transesterification reactions* (Figure 8-8). Introns are removed as a lariat structure in which the 5' G of the intron is joined in an unusual 2',5'-phosphodiester bond to an adenosine near the 3' end of the intron. This A residue is called the *branch point* A because it forms an RNA branch in the lariat structure. In each transesterification reaction, one phosphoester bond is exchanged for another. Since the number of phosphoester bonds in the molecule is not changed in either reaction, no energy is consumed. The

net result of these two reactions is that two exons are ligated and the intervening intron is released as a branched lariat structure.

During Splicing, snRNAs Base-Pair with Pre-mRNA

Splicing requires the presence of **small nuclear RNAs (snRNAs)**, important for base pairing with the pre-mRNA, and ~170 associated proteins. Five U-rich snRNAs, designated U1, U2, U4, U5, and U6, participate in pre-mRNA splicing. Ranging in length from 107–210 nucleotides, these snRNAs are associated with 6–10 proteins each in the many

FIGURE 8-7 Consensus sequences around splice sites in vertebrate pre-mRNAs. The only nearly invariant bases are the 5' GU and the 3' AG of the intron (blue), although the flanking bases indicated are found at frequencies higher than expected based on a random distribution. A pyrimidine-rich region (hatch marked) near the 3' end of the intron is found in most cases. The branch-point

adenosine, also invariant, usually is 20–50 bases from the 3' splice site. The central region of the intron, which may range from 40 bases to 50 kilobases in length, generally is unnecessary for splicing to occur. [See R. A. Padgett et al., 1986, *Ann. Rev. Biochem.* 55:1119, and E. B. Keller and W. A. Noon, 1984, *Proc. Nat'l. Acad. Sci. USA* 81:7417.]

FIGURE 8-8 Two transesterification reactions that result in splicing of exons in pre-mRNA. In the first reaction, the ester bond between the 5' phosphorus of the intron and the 3' oxygen (dark red) of exon 1 is exchanged for an ester bond with the 2' oxygen (blue) of the branch-site A residue. In the second reaction, the ester bond between the 5' phosphorus of exon 2 and the 3' oxygen (orange) of the intron is exchanged for an ester bond with the 3' oxygen of exon 1, releasing the intron as a lariat structure and joining the two exons. Arrows show where activated hydroxyl oxygens react with phosphorus atoms.

small nuclear ribonucleoprotein particles (snRNPs) in the nuclei of eukaryotic cells.

Definitive evidence for the role of U1 snRNA in splicing came from experiments indicating that base pairing between the 5' splice site of a pre-mRNA and the 5' region of U1 snRNA is required for RNA splicing (Figure 8-9a). In vitro experiments showed that a synthetic oligonucleotide that hybridizes with the 5'-end region of U1 snRNA blocks RNA splicing. In vivo experiments showed that base-pairing-disrupting mutations in the pre-mRNA 5' splice site also block RNA splicing; in this case, however, splicing can be restored by expression of a mutant U1 snRNA with a compensating mutation that restores base pairing to the mutant pre-mRNA 5' splice site

(Figure 8-9b). Involvement of U2 snRNA in splicing initially was suspected when it was found to have an internal sequence that is largely complementary to the consensus sequence flanking the branch point in pre-mRNAs (see Figure 8-7). Compensating mutation experiments, similar to those conducted with U1 snRNA and 5' splice sites, demonstrated that base pairing between U2 snRNA and the branch-point sequence in pre-mRNA also is critical to splicing.

Figure 8-9a illustrates the general structures of the U1 and U2 snRNAs and how they base-pair with pre-mRNA during splicing. Significantly, the branch-point A itself, which is not base-paired to U2 snRNA, “bulges out” (Figure 8-10a), allowing its 2' hydroxyl to participate in the first transesterification reaction of RNA splicing (see Figure 8-8).

Similar studies with other snRNAs demonstrated that base pairing between them also occurs during splicing. Moreover, rearrangements in these RNA-RNA interactions are critical in the splicing pathway, as we describe next.

Spliceosomes, Assembled from snRNPs and a Pre-mRNA, Carry Out Splicing

The five splicing snRNPs and other proteins involved in splicing assemble on a pre-mRNA, forming a large ribonucleoprotein complex called a **spliceosome** (Figure 8-11). The spliceosome has a mass similar to that of a ribosome. Assembly of a spliceosome begins with the base pairing of the U1 snRNA to the 5' splice site and the cooperative binding of protein SF1 (splicing factor 1) to the branch point A and the heterodimeric protein U2AF (U2 associated factor) to the pyrimidine tract and the 3' AG of the intron via its large and small subunits, respectively. The U2 snRNP then base-pairs with the branch point region (Figure 8-9a) as SF1 is released. Extensive base pairing between the snRNAs in the U4 and U6 snRNPs forms a complex that associates with U5 snRNP. The U4/U6/U5 “tri-snRNP” then associates with the previously formed U1/U2/pre-mRNA complex to generate a spliceosome.

After formation of the spliceosome, extensive rearrangements in the pairing of snRNAs and the pre-mRNA lead to release of the U1 snRNP. Figure 8-10b shows a cryoelectron-microscopy structure of this intermediate in the splicing process. A further rearrangement of spliceosomal components occurs with the loss of U4 snRNP. This generates a complex that catalyzes the first transesterification reaction that forms the 2',5'-phosphodiester bond between the 2' hydroxyl on the branch point A and the phosphate at the 5' end of the intron (Figure 8-9). Following another rearrangement of the snRNPs, the second transesterification reaction ligates the two exons in a standard 3',5'-phosphodiester bond, releasing the intron as a lariat structure associated with the snRNPs. This final intron-snRNP complex rapidly dissociates, and the individual snRNPs released can participate in a new cycle of splicing. The excised intron is then rapidly degraded by a debranching enzyme and other nuclear RNases discussed later.

As mentioned above, a spliceosome is roughly the size of a ribosome and is composed of ~170 proteins, including ~100 “splicing factors” in addition to the proteins associated with the

FOCUS ANIMATION: mRNA Splicing

FIGURE 8-9 Base pairing between pre-mRNA, U1 snRNA, and U2 snRNA early in the splicing process. (a) In this diagram, secondary structures in the snRNAs that are not altered during splicing are depicted schematically. The yeast branch-point sequence is shown here. Note that U2 snRNA base-pairs with a sequence that includes the branch-point A, although this residue is not base-paired. The purple rectangles represent sequences that bind snRNP proteins recognized by anti-Sm antibodies. For unknown reasons, antisera from patients with the autoimmune disease systemic lupus erythematosus (SLE) contain antibodies to snRNP proteins, which have been useful in

characterizing components of the splicing reaction. (b) Only the 5' ends of U1 snRNAs and 5' splice sites in pre-mRNAs are shown. (Left) A mutation (A) in a pre-mRNA splice site that interferes with base pairing to the 5' end of U1 snRNA blocks splicing. (Right) Expression of a U1 snRNA with a compensating mutation (U) that restores base pairing also restores splicing of the mutant pre-mRNA. [Part (a) adapted from M. J. Moore et al., 1993, in R. Gesteland and J. Atkins, eds., *The RNA World*, Cold Spring Harbor Press, pp. 303–357. Part (b) see Y. Zhuang and A. M. Weiner, 1986, *Cell* 46:827.]

Biophys. Biomol. Struct.* 35:435.]

FOCUS ANIMATION: mRNA Splicing

FIGURE 8-11 Model of spliceosome-mediated splicing of pre-mRNA. Step **1**: After U1 base pairs with the consensus 5' splice site, SF1 (splicing factor 1) binds the branch point A; U2AF (U2 snRNP associated factor) associates with the polypyrimidine tract and 3' splice site; and the U2 snRNP associates with the branch point A via base-pairing interactions shown in Figure 8-9, displacing SF1. Step **2**: A trimeric snRNP complex of U4, U5, and U6 joins the initial complex to form the spliceosome. Step **3**: Rearrangements of base-pairing interactions between snRNAs converts the spliceosome into a catalytically active conformation and destabilizes the U1 and U4 snRNPs, which are released. Step **4**: The catalytic core, thought to be formed by U6 and U2, then catalyzes the first transesterification reaction, forming the intermediate containing a 2',5'-phosphodiester bond as shown in Figure 8-8. Step **5**: Following further rearrangements between the snRNPs, the second transesterification reaction joins the two exons by a standard 3',5'-phosphodiester bond and releases the intron as a lariat structure and the remaining snRNPs. Step **6**: The excised lariat intron is converted into a linear RNA by a debranching enzyme. [Adapted from T. Villa et al., 2002, *Cell* 109:149.]

five snRNPs. This makes RNA splicing comparable in complexity to initiation of transcription and protein synthesis. Some of the splicing factors are associated with snRNPs, but others are not. For instance, the 65-kD subunit of the U2-associated factor (U2AF) binds to the pyrimidine-rich region near the 3' end of introns and to the U2 snRNP. The 35-kD subunit of U2AF binds to the AG dinucleotide at the 3' end of the intron and also interacts with the larger U2AF subunit bound nearby. These two U2AF subunits act together with SF1 to help specify the 3' splice site by promoting interaction of U2 snRNP with the branch point (see Figure 8-11, step **1**). Some splicing factors also exhibit sequence homologies to known RNA helicases; these are probably necessary for the base-pairing rearrangements that occur in snRNAs during the spliceosomal splicing cycle.

Following RNA splicing, a specific set of hnRNP proteins remain bound to the spliced RNA approximately 20 nucleotides 5' to each exon-exon junction, thus forming an *exon-junction complex*. One of the hnRNP proteins associated with the exon-junction complex is the RNA export factor (REF), which functions in the export of fully processed mRNPs from the nucleus to the cytoplasm, as discussed in Section 8.3. Other proteins associated with the exon-junction complex function in a quality-control mechanism that leads to the degradation of improperly spliced mRNAs, known as nonsense-mediated decay (Section 8.4).

A small fraction of pre-mRNAs (<1% in humans) contain introns whose splice sites do not conform to the standard consensus sequence. This class of introns begins with AU and ends with AC rather than following the usual "GU-AG rule" (see Figure 8-7). Splicing of this special class of introns occurs via a splicing cycle analogous to that shown in Figure 8-11, except that four novel, low-abundance snRNPs, together with the standard U5 snRNP, are involved.

Nearly all functional mRNAs in vertebrate, insect, and plant cells are derived from a single molecule of the corre-

sponding pre-mRNA by removal of internal introns and splicing of exons. However, in two types of protozoans—trypanosomes and euglenoids—mRNAs are constructed by splicing together separate RNA molecules. This process, referred to as *trans-splicing*, is also used in the synthesis of

FIGURE 8-12 Schematic diagram of RNA polymerase II with the CTD extended. The length of the fully extended yeast RNA polymerase II carboxyl-terminal domain (CTD) and the linker region that connects it to the polymerase is shown relative to the globular domain of the

polymerase. The CTD of mammalian RNA polymerase II is twice as long. In its extended form, the CTD can associate with multiple RNA-processing factors simultaneously. [From P. Cramer, D. A. Bushnell, and R. D. Kornberg, 2001, *Science* **292**:1863.]

10–15 percent of the mRNAs in the nematode (roundworm) *Caenorhabditis elegans*, an important model organism for studying embryonic development. Trans-splicing is carried out by snRNPs by a process similar to the splicing of exons in a single pre-mRNA.

Chain Elongation by RNA Polymerase II Is Coupled to the Presence of RNA-Processing Factors

How is RNA processing efficiently coupled with the transcription of a pre-mRNA? The key lies in the long carboxyl-terminal domain (CTD) of RNA polymerase II, which, as discussed in Chapter 7, is composed of multiple repeats of a seven-residue (heptapeptide) sequence. When fully extended, the CTD domain in the yeast enzyme is about 65 nm long (Figure 8-12); the CTD in human RNA polymerase II is about twice as long. The remarkable length of the CTD apparently allows multiple proteins to associate simultaneously with a single RNA polymerase II molecule. For instance, as mentioned earlier, the enzymes that add the 5' cap to nascent transcripts associate with the CTD phosphorylated on multiple serines at the fifth position in the heptapeptide repeat (Ser-5) during or shortly after transcription initiation by a subunit of TFIIF. In addition, RNA splicing and polyadenylation factors have been found to associate with the phosphorylated CTD. As a consequence, these processing factors are present at high local concentrations when splice sites and poly(A) signals are transcribed by the polymerase, enhancing the rate and specificity of RNA processing. In a reciprocal fashion, the association of hnRNP proteins with the nascent RNA enhances the interaction of RNA polymerase II with elongation factors such as DSIF and CDK9-cyclin T (P-TEFb) (Figure 7-20), increasing the rate of transcription. As a consequence, the rate of transcription is coordinated with the rate of nascent RNA association with hnRNPs and RNA-processing factors. This mechanism may ensure that a pre-mRNA is not synthesized unless the machinery for processing it is properly positioned.

SR Proteins Contribute to Exon Definition in Long Pre-mRNAs

The average length of an exon in the human genome is ~150 bases, whereas the average length of an intron is much longer

(~3500 bases). The longest introns contain upward of 500 kb! Because the sequences of 5' and 3' splice sites and branch points are so degenerate, multiple copies are likely to occur randomly in long introns. Consequently, additional sequence information is required to define the exons that should be spliced together in higher organisms with long introns.

The information for defining the splice sites that demarcate exons is encoded within the sequences of the exons. A family of RNA-binding proteins, the *SR proteins*, interact with sequences within exons called *exonic splicing enhancers*. SR proteins are a subset of the hnRNP proteins discussed earlier and so contain one or more RRM RNA-binding domains. They also contain several protein-protein interaction domains rich in arginine (R) and serine (S) residues called RS domains. When bound to exonic splicing enhancers, SR proteins mediate the cooperative binding of U1 snRNP to a true 5' splice site and U2 snRNP to a branch point through a network of protein-protein interactions that span an exon (Figure 8-13). The complex of SR proteins, snRNPs, and other splicing factors (e.g., U2AF) that assemble across an exon, which has been called a *cross-exon recognition complex*, permits precise specification of exons in long pre-mRNAs.

 In the transcription units of higher organisms with long introns, exons not only encode the amino acid sequences of different portions of a protein but also contain binding sites for SR proteins. Mutations that interfere with the binding of an SR protein to an exonic splicing enhancer, even if they do not change the encoded amino acid sequence, prevent formation of the cross-exon recognition complex. As a result, the affected exon is “skipped” during splicing and is not included in the final processed mRNA. The truncated mRNA produced in this case is either degraded or translated into a mutant, abnormally functioning protein. This type of mutation occurs in some human genetic diseases. For example, *spinal muscular atrophy* is one of the most common genetic causes of childhood mortality. This disease results from mutations in a region of the genome containing two closely related genes, *SMN1* and *SMN2*, that arose by gene duplication. *SMN2* encodes a protein identical with *SMN1*. *SMN2* is expressed at a much lower level because a silent mutation in one exon interferes with the binding of an SR protein. This leads to exon skipping in most of the *SMN2* mRNAs. The homologous *SMN* gene in the mouse, where there is

FIGURE 8-13 Exon recognition through cooperative binding of SR proteins and splicing factors to pre-mRNA. The correct 5' GU and 3' AG splice sites are recognized by splicing factors on the basis of their proximity to exons. The exons contain exonic splicing enhancers (ESEs) that are binding sites for SR proteins. When bound to ESEs, the SR proteins interact with one another and promote the cooperative binding of the U1 snRNP to the 5' splice site of the downstream intron, SF1 and then the U2 snRNP to the branch point of the upstream intron, the 65- and 35-kD subunits of U2AF to the pyrimidine-rich region and AG 3' splice site of the upstream intron, and other splicing factors (not shown). The resulting RNA-protein cross-exon recognition complex

spans an exon and activates the correct splice sites for RNA splicing. Note that the U1 and U2 snRNPs in this unit do not become part of the same spliceosome. The U2 snRNP on the right forms a spliceosome with the U1 snRNP bound to the 5' end of the same intron. The U1 snRNP shown on the right forms a spliceosome with the U2 snRNP bound to the branch point of the downstream intron (not shown), and the U2 snRNP on the left forms a spliceosome with a U1 snRNP bound to the 5' splice site of the upstream intron (not shown). Double-headed arrows indicate protein-protein interactions. [Adapted from T. Maniatis, 2002, *Nature* **418**:236; see also S. M. Berget, 1995, *J. Biol. Chem.* **270**:2411.]

only a single copy, is essential for cell viability. Spinal muscular atrophy in humans results from homozygous mutations that inactivate *SMN1*. The low level of protein translated from the small fraction of *SMN2* mRNAs that are correctly spliced is sufficient to maintain cell viability during embryogenesis and fetal development, but it is not sufficient to maintain viability of spinal cord motor neurons in childhood, resulting in their death and the associated disease.

Approximately 15 percent of the single-base-pair mutations that cause human genetic diseases interfere with proper *exon definition*. Some of these mutations occur in 5' or 3' splice sites, often resulting in the use of nearby alternative "cryptic" splice sites present in the normal gene sequence. In the absence of the normal splice site, the cross-exon recognition complex recognizes these alternative sites. Other mutations that cause abnormal splicing result in a new consensus splice-site sequence that becomes recognized in place of the normal splice site. Finally, some mutations can interfere with the binding of specific SR proteins to pre-mRNAs. These mutations inhibit splicing at normal splice sites, as in the case of the *SMN2* gene, and thus lead to exon skipping. ■

Self-Splicing Group II Introns Provide Clues to the Evolution of snRNAs

Under certain nonphysiological *in vitro* conditions, pure preparations of some RNA transcripts slowly splice out introns in the absence of any protein. This observation led to the recognition that some introns are *self-splicing*. Two types of self-splicing introns have been discovered: *group I introns*, present in nuclear rRNA genes of protozoans, and *group II introns*, present in protein-coding genes and some rRNA and tRNA genes in mitochondria and chloroplasts of plants and

fungi. Discovery of the catalytic activity of self-splicing introns revolutionized concepts about the functions of RNA. As discussed in Chapter 4, RNA is now known to catalyze peptide-bond formation during protein synthesis in ribosomes. Here we discuss the probable role of group II introns, now found only in mitochondrial and chloroplast DNA, in the evolution of snRNAs; the functioning of group I introns is considered in the later section on rRNA processing.

Even though their precise sequences are not highly conserved, all group II introns fold into a conserved, complex secondary structure containing numerous stem loops (Figure 8-14a). Self-splicing by a group II intron occurs via two transesterification reactions, involving intermediates and products analogous to those found in nuclear pre-mRNA splicing. The mechanistic similarities between group II intron self-splicing and spliceosomal splicing led to the hypothesis that snRNAs function analogously to the stem loops in the secondary structure of group II introns. According to this hypothesis, snRNAs interact with 5' and 3' splice sites of pre-mRNAs and with each other to produce a three-dimensional RNA structure functionally analogous to that of group II self-splicing introns (Figure 8-14b).

An extension of this hypothesis is that introns in ancient pre-mRNAs evolved from group II self-splicing introns through the progressive loss of internal RNA structures, which concurrently evolved into trans-acting snRNAs that perform the same functions. Support for this type of evolutionary model comes from experiments with group II intron mutants in which domain V and part of domain I are deleted. RNA transcripts containing such mutant introns are defective in self-splicing, but when RNA molecules equivalent to the deleted regions are added to the *in vitro* reaction, self-splicing occurs. This finding demonstrates that these domains in group II introns can be trans-acting, like snRNAs.

FIGURE 8-14 Comparison of group II self-splicing introns and the spliceosome. The schematic diagrams compare the secondary structures of (a) group II self-splicing introns and (b) U snRNAs present in the spliceosome. The first transesterification reaction is indicated by light green arrows; the second reaction, by blue arrows. The branch point A is boldfaced. The similarity in these structures suggests that the spliceosomal snRNAs evolved from group II introns, with the trans-acting snRNAs being functionally analogous to the corresponding domains in group II introns. The colored bars flanking the introns in (a) and (b) represent exons. [Adapted from P. A. Sharp, 1991, *Science* 254:663.]

The similarity in the mechanisms of group II intron self-splicing and spliceosomal splicing of pre-mRNAs also suggests that the splicing reaction is catalyzed by the snRNA, not the protein, components of spliceosomes. Although group II introns can self-splice *in vitro* at elevated temperatures and Mg^{2+} concentrations, under *in vivo* conditions proteins called *maturases*, which bind to group II intron RNA, are required for rapid splicing. Maturases are thought to stabilize the precise three-dimensional interactions of the intron RNA required to catalyze the two splicing transesterification reactions. By analogy, snRNP proteins in spliceosomes are thought to stabilize the precise geometry of snRNAs and intron nucleotides required to catalyze pre-mRNA splicing.

The evolution of snRNAs may have been an important step in the rapid evolution of higher eukaryotes. As internal intron sequences were lost and their functions in RNA splicing supplanted by trans-acting snRNAs, the remaining intron sequences would be free to diverge. This in turn likely facilitated the evolution of new genes through **exon shuffling** since there are few constraints on the sequence of new introns generated in the process (see Figures 6-18 and 6-19). It also permitted the increase in protein diversity that results from alternative RNA splicing and an additional level of gene control resulting from regulated RNA splicing.

3' Cleavage and Polyadenylation of Pre-mRNAs Are Tightly Coupled

In eukaryotic cells, all mRNAs, except histone mRNAs, have a 3' *poly(A) tail*. (The major histone mRNAs are transcribed from repeated genes at prodigious levels in replicating cells during the S phase. They undergo a special form of 3'-end

processing that involves cleavage but not polyadenylation. Specialized RNA-binding proteins that help to regulate histone mRNA translation bind to the 3' end generated by this specialized system.) Early studies of pulse-labeled adenovirus and SV40 RNA demonstrated that the viral primary transcripts extend beyond the site from which the poly(A) tail extends. These results suggested that A residues are added to a 3' hydroxyl generated by endonucleolytic cleavage of a longer transcript, but the predicted downstream RNA fragments never were detected *in vivo*, presumably because of their rapid degradation. However, detection of both predicted cleavage products was observed in *in vitro* processing reactions performed with nuclear extracts of cultured human cells. The cleavage/polyadenylation process and degradation of the RNA downstream of the cleavage site occurs much more slowly in these *in vitro* reactions, simplifying detection of the downstream cleavage product.

Early sequencing of cDNA clones from animal cells showed that nearly all mRNAs contain the sequence AAUAAA 10–35 nucleotides *upstream* from the poly(A) tail (Figure 8-15). Polyadenylation of RNA transcripts is virtually eliminated when the corresponding sequence in the template DNA is mutated to any other sequence except one encoding a closely related sequence (AUUAAA). The unprocessed RNA transcripts produced from such mutant templates do not accumulate in nuclei but are rapidly degraded. Further mutagenesis studies revealed that a second signal downstream from the cleavage site is required for efficient cleavage and polyadenylation of most pre-mRNAs in animal cells. This downstream signal is not a specific sequence but rather a GU-rich or simply a U-rich region within ~50 nucleotides of the cleavage site.

Identification and purification of the proteins required for cleavage and polyadenylation of pre-mRNA have led to the model shown in Figure 8-15. A 360-kDa cleavage and polyadenylation specificity factor (CPSF), composed of five different polypeptides, first forms an unstable complex with the upstream AAUAAA poly(A) signal. Then at least three additional proteins bind to the CPSF-RNA complex: a 200-kDa heterotrimer called *cleavage stimulatory factor* (CStF), which interacts with the GU-rich sequence; a 150-kDa heterotetramer called *cleavage factor I* (CFI); and a second heterodimeric cleavage factor (CFII). An ~150-kDa protein called *symplekin* is thought to form a scaffold on which these cleavage/polyadenylation factors assemble. Finally, *poly(A) polymerase* (PAP) binds to the complex *before* cleavage can occur. This requirement for PAP binding links cleavage and polyadenylation, so that the free 3' end generated is rapidly polyadenylated and no essential information is lost to exonuclease degradation of an unprotected 3' end.

Assembly of the large, multiprotein **cleavage/polyadenylation complex** around the AU-rich poly(A) signal in a pre-mRNA is analogous in many ways to formation of the transcription-preinitiation complex at the AT-rich TATA box of a template DNA molecule (see Figure 7-16). In both cases, multiprotein complexes assemble cooperatively through a network of specific protein–nucleic acid and protein–protein interactions.

FIGURE 8-15 Model for cleavage and polyadenylation of pre-mRNAs in mammalian cells. Cleavage and polyadenylation specificity factor (CPSF) binds to the upstream AAUAAA poly(A) signal. CSTF interacts with a downstream GU- or U-rich sequence and with bound CPSF, forming a loop in the RNA; binding of CFI and CFII helps stabilize the complex. Binding of poly(A) polymerase (PAP) then stimulates cleavage at a poly(A) site, which usually is 10–35 nucleotides 3' of the upstream poly(A) signal. The cleavage factors are released, as is the downstream RNA cleavage product, which is rapidly degraded. Bound PAP then adds ~12 A residues at a slow rate to the 3'-hydroxyl group generated by the cleavage reaction. Binding of poly(A)-binding protein II (PABPII) to the initial short poly(A) tail accelerates the rate of addition by PAP. After 200–250 A residues have been added, PABPII signals PAP to stop polymerization.

Following cleavage at the poly(A) site, polyadenylation proceeds in two phases. Addition of the first 12 or so A residues occurs slowly, followed by rapid addition of up to 200–250 more A residues. The rapid phase requires the binding of multiple copies of a *poly(A)-binding protein* containing the RRM motif. This protein is designated *PABPII* to distinguish it from the poly(A)-binding protein present in the cytoplasm. PABPII binds to the short A tail initially added by PAP, stimulating the rate of polymerization of additional A residues by PAP, resulting in the fast phase of polyadenylation (Figure 8-15). PABPII is also responsible for signaling poly(A) polymerase to terminate polymerization when the poly(A) tail reaches a length of 200–250 residues, although the mechanism for controlling the length of the tail is not yet understood. Binding of PABPII to the poly(A) tail is essential for mRNA export into the cytoplasm.

Nuclear Exonucleases Degrade RNA That Is Processed Out of Pre-mRNAs

Because the human genome contains long introns, only ~5 percent of the nucleotides that are polymerized by RNA polymerase II during transcription are retained in mature, processed mRNAs. Although this process appears inefficient, it probably evolved in multicellular organisms because the process of exon shuffling facilitated the evolution of new genes in organisms with long introns (Chapter 6). The introns that are spliced out and the region downstream from the cleavage and polyadenylation site are degraded by nuclear exonucleases that hydrolyze one base at a time from either the 5' or 3' end of an RNA strand.

As mentioned earlier, the 2',5'-phosphodiester bond in excised introns is hydrolyzed by a debranching enzyme, yielding a linear molecule with unprotected ends that can be attacked by exonucleases (see Figure 8-11). The predominant nuclear decay pathway is 3'→5' hydrolysis by 11 exonucleases that associate with one another in a large protein complex called the *exosome*. Other proteins in the complex include RNA helicases that disrupt base pairing and RNA-protein interactions that would otherwise impede the exonucleases. Exosomes also function in the cytoplasm, as discussed

later. In addition to introns, the exosome appears to degrade pre-mRNAs that have not been properly spliced or polyadenylated. It is not yet clear how the exosome recognizes improperly processed pre-mRNAs. But in yeast cells with temperature-sensitive mutant poly(A) polymerase (Figure 8-15), pre-mRNAs are retained at their sites of transcription in the nucleus at the nonpermissive temperature. These abnormally processed pre-mRNAs are released in cells with a second mutation in a subunit of the exosome found only in nuclear and not in cytoplasmic exosomes (PM-Scl; 100 kD in humans). Also, exosomes are found concentrated at sites of transcription in *Drosophila* polytene chromosomes, where they are associated with RNA polymerase II elongation factors. These results suggest that the exosome participates in an as yet poorly understood quality-control mechanism that recognizes aberrantly processed pre-mRNAs, preventing their export to the cytoplasm and ultimately leading to their degradation.

To avoid being degraded by nuclear exonucleases, nascent transcripts, pre-mRNA processing intermediates, and mature mRNAs in the nucleus must have their ends protected. As discussed above, the 5' end of a nascent transcript is protected by addition of the 5' cap structure as soon as the 5' end emerges from the polymerase. The 5' cap is protected because it is bound by a *nuclear cap-binding complex*, which protects it from 5' exonucleases and also functions in export of mRNA to the cytoplasm. The 3' end of a nascent transcript lies within the RNA polymerase and thus is inaccessible to exonucleases (see Figure 4-12). As discussed previously, the free 3' end generated by cleavage of a pre-mRNA downstream from the poly(A) signal is rapidly polyadenylated by the poly(A) polymerase associated with the other 3' processing factors, and the resulting poly(A) tail is bound by PABPII (Figure 8-15). This tight coupling of cleavage and polyadenylation protects the 3' end from exonuclease attack.

KEY CONCEPTS of Section 8.1

Processing of Eukaryotic Pre-mRNA

- In the nucleus of eukaryotic cells, pre-mRNAs are associated with hnRNP proteins and processed by 5' capping, 3' cleavage and polyadenylation, and splicing before being transported to the cytoplasm (see Figure 8-2).
- Shortly after transcription initiation, capping enzymes associated with the carboxyl-terminal domain (CTD) of RNA polymerase II, which is phosphorylated multiple times at serine 5 of the heptapeptide repeat by TFIIH during transcription initiation, add the 5' cap to the nascent transcript. Other RNA-processing factors involved in RNA splicing, 3' cleavage, and polyadenylation associate with the CTD when it is phosphorylated at serine 2 of the heptapeptide repeat, increasing the rate of transcription elongation. Consequently, transcription does not proceed at a high rate until RNA-processing factors be-

come associated with the CTD, where they are poised to interact with the nascent pre-mRNA as it emerges from the surface of the polymerase.

- Five different snRNPs interact via base pairing with one another and with pre-mRNA to form the spliceosome (see Figure 8-11). This very large ribonucleoprotein complex catalyzes two transesterification reactions that join two exons and remove the intron as a lariat structure, which is subsequently degraded (see Figure 8-8).
- SR proteins that bind to *exonic splicing enhancer* sequences in exons are critical in defining exons in the large pre-mRNAs of higher organisms. A network of interactions between SR proteins, snRNPs, and splicing factors forms a cross-exon recognition complex that specifies correct splice sites (see Figure 8-13).
- The snRNAs in the spliceosome are thought to have an overall tertiary structure similar to that of group II self-splicing introns.
- For long transcription units in higher organisms, splicing of exons usually begins as the pre-mRNA is still being formed. Cleavage and polyadenylation to form the 3' end of the mRNA occur after the poly(A) site is transcribed.
- In most protein-coding genes, a conserved AAUAAA poly(A) signal lies slightly upstream from a poly(A) site where cleavage and polyadenylation occur. A GU- or U-rich sequence downstream from the poly(A) site contributes to the efficiency of cleavage and polyadenylation.
- A multiprotein complex that includes poly(A) polymerase (PAP) carries out the cleavage and polyadenylation of a pre-mRNA. A nuclear poly(A)-binding protein, PABPII, stimulates addition of A residues by PAP and stops addition once the poly(A) tail reaches 200–250 residues (see Figure 8-15).
- Excised introns and RNA downstream from the cleavage/poly(A) site are degraded primarily by exosomes, multiprotein complexes that contain eleven 3'→5' exonucleases as well as RNA helicases. Exosomes also degrade improperly processed pre-mRNAs.

8.2 Regulation of Pre-mRNA Processing

Now that we've seen how pre-mRNAs are processed into mature, functional mRNAs, we consider how regulation of this process can contribute to gene control. Recall from Chapter 6 that higher eukaryotes contain both simple and complex transcription units encoded in their DNA. The primary transcripts produced from the former contain one poly(A) site and exhibit only one pattern of RNA splicing, even if multiple introns are present; thus simple transcription units encode a single mRNA. In contrast, the primary transcripts produced from complex transcription units (~92–94% of all human transcription units) can be processed in alternative ways to yield different mRNAs that encode distinct proteins (see Figure 6-3).

Alternative Splicing Generates Transcripts with Different Combinations of Exons

The discovery that a large fraction of transcription units in higher organisms encode alternatively spliced mRNAs and that differently spliced mRNAs are expressed in different cell types revealed that regulation of RNA splicing is an important gene-control mechanism in higher eukaryotes. Although many examples of cleavage at alternative poly(A) sites in pre-mRNAs are known, **alternative splicing** of different exons is the more common mechanism for expressing different proteins from one complex transcription unit. In Chapter 4, for example, we mentioned that fibroblasts produce one type of the extracellular protein fibronectin, whereas hepatocytes produce another type. Both fibronectin **isoforms** are encoded by the same transcription unit, which is spliced differently in the two cell types to yield two different mRNAs (see Figure 4-16). In other cases, alternative processing may occur simultaneously in the same cell type in response to different developmental or environmental signals. First we discuss one of the best-understood examples of regulated RNA processing and then we briefly consider the consequences of RNA splicing in the development of the nervous system.

A Cascade of Regulated RNA Splicing Controls *Drosophila* Sexual Differentiation

One of the earliest examples of regulated alternative splicing of pre-mRNA came from studies of sexual differentiation in *Drosophila*. Genes required for normal *Drosophila* sexual differentiation were first characterized by isolating *Drosophila* mutants defective in the process. When the proteins encoded by the wild-type genes were characterized biochemically, two of them were found to regulate a cascade of alternative RNA splicing in *Drosophila* embryos. More recent research has provided insight into how these proteins regulate RNA processing and ultimately lead to the creation of two different sex-specific transcriptional repressors that suppress the development of characteristics of the opposite sex.

The Sxl protein, encoded by the *sex-lethal* gene, is the first protein to act in the cascade (Figure 8-16). The Sxl protein is present only in female embryos. Early in development, the gene is transcribed from a promoter that functions only in female embryos. Later in development, this female-specific promoter is shut off and another promoter for *sex-lethal* becomes active in both male and female embryos. However, in the absence of early Sxl protein, the *sex-lethal* pre-mRNA in

FIGURE 8-16 Cascade of regulated splicing that controls sex determination in *Drosophila* embryos. For clarity, only the exons (boxes) and Introns (black lines) where regulated splicing occurs are shown. Splicing is indicated by red dashed lines above (female) and blue dashed lines below (male) the pre-mRNAs. Vertical red lines in exons indicate in-frame stop codons, which prevent synthesis of functional protein. Only female embryos produce functional Sxl protein, which represses splicing between exons 2 and 3 in *sxl* pre-mRNA (a) and between exons 1 and 2 in *tra* pre-mRNA (b). (c) In contrast, the cooperative binding of Tra protein and two SR proteins,

Rbp1 and Tra2, activates splicing between exons 3 and 4 and cleavage/polyadenylation (A_n) at the 3' end of exon 4 in *dsx* pre-mRNA in female embryos. In male embryos, which lack functional Tra, the SR proteins do not bind to exon 4, and consequently exon 3 is spliced to exon 5. The distinct Dsx proteins produced in female and male embryos as the result of this cascade of regulated splicing repress transcription of genes required for sexual differentiation of the opposite sex. [Adapted from M. J. Moore et al., 1993, in R. Gesteland and J. Atkins, eds., *The RNA World*, Cold Spring Harbor Press, pp. 303–357.]

male embryos is spliced to produce an mRNA that contains a stop codon early in the sequence. The net result is that male embryos produce no functional Sxl protein either early or later in development.

In contrast, the Sxl protein expressed in early female embryos directs splicing of the *sex-lethal* pre-mRNA so that a functional *sex-lethal* mRNA is produced (Figure 8-16a). Sxl accomplishes this by binding to a sequence in the pre-mRNA near the 3' end of the intron between exon 2 and exon 3, thereby blocking the proper association of U2AF and U2 snRNP (Figure 8-11). As a consequence, the U1 snRNP bound to the 3' end of exon 2 assembles into a spliceosome with U2 snRNP bound to the branch point at the 3' end of the intron between exons 3 and 4, leading to splicing of exon 2 to exon 4 and skipping of exon 3. The binding site for Sxl in the Sxl pre-mRNA is called an *intronic splicing silencer* because of its location in an intron and its function in blocking, or “silencing,” use of a splice site. The resulting female-specific *sex-lethal* mRNA is translated into functional Sxl protein, which reinforces its own expression in female embryos by continuing to cause skipping of exon 3. The absence of Sxl protein in male embryos allows the inclusion of exon 3 and, consequently, of the stop codon that prevents translation of functional Sxl protein.

Sxl protein also regulates alternative RNA splicing of the *transformer* gene pre-mRNA (Figure 8-16b). In male embryos, where no Sxl is expressed, exon 1 is spliced to exon 2, which contains a stop codon that prevents synthesis of a functional *transformer* protein. In female embryos, however, binding of Sxl protein to an intronic splicing silencer at the 3' end of the intron between exons 1 and 2 blocks binding of U2AF at this site. The interaction of Sxl with *transformer* pre-mRNA is mediated by two RRM domains in the protein (see Figure 8-5). When Sxl is bound, U2AF binds to a lower-affinity site farther 3' in the pre-mRNA; as a result exon 1 is spliced to this alternative 3' splice site, eliminating exon 2 with its stop codon. The resulting female-specific *transformer* mRNA, which contains additional constitutively spliced exons, is translated into functional Transformer (Tra) protein.

Finally, Tra protein regulates the alternative processing of pre-mRNA transcribed from the *double-sex* gene (Figure 8-16c). In female embryos, a complex of Tra and two constitutively expressed proteins, Rbp1 and Tra2, directs splicing of exon 3 to exon 4 and also promotes cleavage/polyadenylation at the alternative poly(A) site at the 3' end of exon 4—leading to a short, female-specific version of the Dsx protein. In male embryos, which produce no Tra protein, exon 4 is skipped, so that exon 3 is spliced to exon 5. Exon 5 is constitutively spliced to exon 6, which is polyadenylated at its 3' end—leading to a longer, male-specific version of the Dsx protein. The RNA sequence to which Tra binds in exon 4 is called an *exonic splicing enhancer* since it enhances splicing at a nearby splice site.

As a result of the cascade of regulated RNA processing depicted in Figure 8-16, different Dsx proteins are expressed in male and female embryos. The male Dsx protein is a transcriptional repressor that inhibits the expression of genes required

FIGURE 8-17 Model of splicing activation by Tra protein and the SR proteins Rbp1 and Tra2. In female *Drosophila* embryos, splicing of exons 3 and 4 in *dsx* pre-mRNA is activated by binding of Tra/Tra2/Rbp1 complexes to six sites in exon 4. Because Rbp1 and Tra2 cannot bind to the pre-mRNA in the absence of Tra, exon 4 is skipped in male embryos. See the text for discussion. A_n = polyadenylation. [Adapted from T. Maniatis and B. Tasic, 2002, *Nature* **418**:236.]

for female development. Conversely, the female Dsx protein represses transcription of genes required for male development.

Figure 8-17 illustrates how the Tra/Tra2/Rbp1 complex is thought to interact with *double-sex* (*dsx*) pre-mRNA. Rbp1 and Tra2 are SR proteins, but they do not interact with exon 4 in the absence of the Tra protein. Tra protein interacts with Rbp1 and Tra2, resulting in the cooperative binding of all three proteins to six exonic splicing enhancers in exon 4. The bound Tra2 and Rbp1 proteins then promote the binding of U2AF and U2 snRNP to the 3' end of the intron between exons 3 and 4, just as other SR proteins do for constitutively spliced exons (see Figure 8-13). The Tra/Tra2/Rbp1 complexes may also enhance binding of the cleavage/polyadenylation complex to the 3' end of exon 4.

Splicing Repressors and Activators Control Splicing at Alternative Sites

As is evident from Figure 8-16, the *Drosophila* Sxl protein and Tra protein have opposite effects: Sxl prevents splicing, causing exons to be skipped, whereas Tra promotes splicing. The action of similar proteins may explain the cell-type-specific expression of fibronectin isoforms in humans. For instance, an Sxl-like splicing repressor expressed in hepatocytes might bind to splice sites for the EIIIA and EIIB exons in the fibronectin pre-mRNA, causing them to be skipped during RNA splicing (see Figure 4-16). Alternatively, a Tra-like splicing activator expressed in fibroblasts might activate the splice sites associated with the fibronectin EIIIA and EIIB exons, leading to inclusion of these exons in the mature mRNA. Experimental examination in some systems has revealed that inclusion of an exon in some cell types versus skipping of the same exon in other cell types results from the combined influence of several splicing repressors and enhancers. RNA binding sites for repressors, usually hnRNP proteins, can also occur in exons, where they are called *exonic splicing silencers*. And binding sites for splicing activators,

usually SR proteins, can also occur in introns, where they are called *intronic splicing enhancers*.

Alternative splicing of exons is especially common in the nervous system, generating multiple isoforms of many proteins required for neuronal development and function in both vertebrates and invertebrates. The primary transcripts from these genes often show complex splicing patterns that can generate several different mRNAs, with different spliced forms expressed in different anatomical locations within the central nervous system. We consider two remarkable examples that illustrate the critical role of this process in neural function.

Expression of K^+ -Channel Proteins in Vertebrate Hair Cells In the inner ear of vertebrates, individual “hair cells,” which are ciliated neurons, respond most strongly to a specific frequency of sound. Cells tuned to low frequency (~ 50 Hz) are found at one end of the tubular cochlea that makes up the inner ear; cells responding to high frequency (~ 5000 Hz) are found at the other end (Figure 8-18a). Cells in between the ends respond to a gradient of frequencies between these extremes. One component in the tuning of hair cells in reptiles and birds is the opening of K^+ ion channels in response to increased intracellular Ca^{2+} concentrations. The Ca^{2+} concentration at which the channel opens determines the frequency with which the membrane potential oscillates and hence the frequency to which the cell is tuned.

The gene encoding this Ca^{2+} -activated K^+ channel is expressed as multiple, alternatively spliced mRNAs. The various proteins encoded by these alternative mRNAs open at different Ca^{2+} concentrations. Hair cells with different response frequencies express different isoforms of the channel protein depending on their position along the length of the cochlea. The sequence variation in the protein is very complex: there are at least eight regions in the mRNA where alternative exons are utilized, permitting the expression of 576 possible isoforms (Figure 8-18b). PCR analysis of mRNAs from individual hair cells has shown that each hair cell expresses a mixture of different alternative Ca^{2+} -activated K^+ -channel mRNAs, with different forms predominating in different cells according to their position along the cochlea. This remarkable arrangement suggests that splicing of the Ca^{2+} -activated K^+ -channel pre-mRNA is regulated in response to extracellular signals that inform the cell of its position along the cochlea.

Other studies demonstrated that splicing at one of the alternative splice sites in the Ca^{2+} -activated K^+ -channel pre-mRNA in the rat is suppressed when a specific protein kinase is activated by neuron depolarization in response to synaptic activity from interacting neurons. This observation raises the possibility that a splicing repressor specific for this site may be activated when it is phosphorylated by this protein kinase, whose activity in turn is regulated by synaptic activity. Since hnRNP and SR proteins are extensively modified by phosphorylation and other post-translational modifications, it seems likely that complex regulation of alternative RNA splicing through post-translational modifications of splicing factors plays a significant role in modulating neuron function.

FIGURE 8-18 Role of alternative splicing in the perception of sounds of different frequency. (a) The chicken cochlea, a 5-mm-long tube, contains an epithelium of auditory hair cells that are tuned to a gradient of vibrational frequencies from 50 Hz at the apical end (left) to 5000 Hz at the basal end (right). (b) The Ca^{2+} -activated K^+ channel contains seven transmembrane α helices (S0–S6), which associate to form the channel. The cytosolic domain, which includes four hydrophobic regions (S7–S10), regulates opening of the channel in response to Ca^{2+} . Isoforms of the channel, encoded by alternatively spliced mRNAs produced from the same primary transcript, open at different Ca^{2+} concentrations and thus respond to different frequencies. Red numbers refer to regions where alternative splicing produces different amino acid sequences in the various isoforms. [Adapted from K. P. Rosenblatt et al., 1997, *Neuron* 19:1061.]

IP Many examples of genes similar to those that encode the cochlear K^+ -channel have been observed in vertebrate neurons; alternatively spliced mRNAs co-expressed from a specific gene in one type of neuron are expressed at different relative concentrations in different regions of the central nervous system. Expansions in the number of microsatellite repeats within the transcribed regions of genes expressed in neurons can cause an alteration in the relative concentrations of alternatively spliced mRNAs transcribed from multiple genes. In Chapter 6, we discussed how backward slippage during DNA replication can lead to expansion of a microsatellite repeat (see Figure 6-5). At least 14 different types of neurological disease result from expansion of microsatellite regions within transcription units expressed in neurons. The resulting long regions of repeated simple sequences in nuclear RNAs of these neurons result in abnormalities in

FIGURE 8-19 RNA editing of *apoB* pre-mRNA. The *apoB* mRNA produced in the liver has the same sequence as the exons in the primary transcript. This mRNA is translated into apoB-100, which has two functional domains: an N-terminal domain (green) that associates with lipids and a C-terminal domain (orange) that binds to LDL

receptors on cell membranes. In the *apoB* mRNA produced in the intestine, the CAA codon in exon 26 is edited to a UAA stop codon. As a result, intestinal cells produce apoB-48, which corresponds to the N-terminal domain of apoB-100. [Adapted from P. Hodges and J. Scott, 1992, *Trends Biochem. Sci.* 17:77.]

the relative concentrations of alternatively spliced mRNAs. For example, the most common of these types of diseases, myotonic dystrophy, is characterized by paralysis, cognitive impairment, and personality and behavior disorders. Myotonic dystrophy results from increased copies of either CUG repeats in one transcript, in some patients, or CCUG repeats in another transcript, in other patients. When the number of these repeats increases to 10 or more times the normal number of repeats in these genes, abnormalities are observed in the level of two hnRNP proteins that bind to these repeated sequences. This probably results because these hnRNPs are bound by the abnormally high concentration of this RNA sequence in the nuclei of neurons in such patients. The abnormal concentrations of these hnRNP proteins are thought to lead to alterations in the rate of splicing of different alternative splice sites in multiple pre-mRNAs normally regulated by these hnRNP proteins. ■

Expression of *Dscam* Isoforms in *Drosophila* Retinal Neurons

The most extreme example of regulated alternative RNA processing yet uncovered occurs in expression of the *Dscam* gene in *Drosophila*. Mutations in this gene interfere with the normal synaptic connections made between axons and dendrites during fly development. Analysis of the *Dscam* gene showed that it contains 95 alternatively spliced exons that could be spliced to generate 38,016 possible isoforms! Recent results have shown that *Drosophila* mutants with a version of the gene that can be spliced in only about 22,000 different ways have specific defects in connectivity between neurons. These results indicate that expression of most of the possible *Dscam* isoforms through regulated RNA splicing helps to specify the tens of millions of different specific synaptic connections between neurons in the *Drosophila* brain. In other words, the correct wiring of neurons in the brain requires regulated RNA splicing.

RNA Editing Alters the Sequences of Some Pre-mRNAs

In the mid-1980s, sequencing of numerous cDNA clones and corresponding genomic DNAs from multiple organisms led to the unexpected discovery of another type of pre-mRNA processing. In this type of processing, called **RNA editing**, the sequence of a pre-mRNA is altered; as a result, the sequence of the corresponding mature mRNA differs from the exons encoding it in genomic DNA.

RNA editing is widespread in the mitochondria of protozoans and plants and also in chloroplasts. In the mitochondria of certain pathogenic trypanosomes, more than half the sequence of some mRNAs is altered from the sequence of the corresponding primary transcripts. Additions and deletions of specific numbers of U's follows templates provided by base-paired short "guide" RNAs. These RNAs are encoded by thousands of mini-mitochondrial DNA circles catenated to many fewer large mitochondrial DNA molecules. The reason for this baroque mechanism for encoding mitochondrial proteins in such protozoans is not clear. But this system does represent a potential target for drugs to inhibit the complex processing enzymes essential to the microbe that do not exist in the cells of their human or other vertebrate hosts.

In higher eukaryotes, RNA editing is much rarer, and thus far, only single-base changes have been observed. Such minor editing, however, turns out to have significant functional consequences in some cases. An important example of RNA editing in mammals involves the *apoB* gene. This gene encodes two alternative forms of a serum protein central to the uptake and transport of cholesterol. Consequently, it is important in the pathogenic processes that lead to *atherosclerosis*, the arterial disease that is the major cause of death in the developed world. The *apoB* gene expresses both the serum protein apolipoprotein B-100 (apoB-100) in hepatocytes, the major cell type in the liver, and apoB-48, expressed

in intestinal epithelial cells. The ~240-kDa apoB-48 corresponds to the N-terminal region of the ~500-kDa apoB-100. As we detail in Chapter 10, both apoB proteins are components of large lipoprotein complexes that transport lipids in the serum. However, only low-density lipoprotein (LDL) complexes, which contain apoB-100 on their surface, deliver cholesterol to body tissues by binding to the LDL receptor present on all cells.

The cell-type-specific expression of the two forms of apoB results from editing of *apoB* pre-mRNA so as to change the nucleotide at position 6666 in the sequence from a C to a U. This alteration, which occurs only in intestinal cells, converts a CAA codon for glutamine to a UAA stop codon, leading to synthesis of the shorter apoB-48 (Figure 8-19). Studies with the partially purified enzyme that performs the post-transcriptional deamination of C₆₆₆₆ to U shows that it can recognize and edit an RNA as short as 26 nucleotides with the sequence surrounding C₆₆₆₆ in the *apoB* primary transcript.

KEY CONCEPTS of Section 8.2

Regulation of Pre-mRNA Processing

- Because of alternative splicing of primary transcripts, the use of alternative promoters, and cleavage at different poly(A) sites, different mRNAs may be expressed from the same gene in different cell types or at different developmental stages (see Figure 6-3 and Figure 8-16).
- Alternative splicing can be regulated by RNA-binding proteins that bind to specific sequences near regulated splice sites. Splicing repressors may sterically block the binding of splicing factors to specific sites in pre-mRNAs or inhibit their function. Splicing activators enhance splicing by interacting with splicing factors, thus promoting their association with a regulated splice site. The RNA sequences bound by splicing repressors are called intronic or exonic splicing silencers, depending on their location in an intron or exon. RNA sequences bound by splicing activators are called intronic or exonic splicing enhancers.
- In RNA editing the nucleotide sequence of a pre-mRNA is altered in the nucleus. In vertebrates, this process is fairly rare and entails deamination of a single base in the mRNA sequence, resulting in a change in the amino acid specified by the corresponding codon and production of a functionally different protein (see Figure 8-19).

8.3 Transport of mRNA Across the Nuclear Envelope

Fully processed mRNAs in the nucleus remain bound by hnRNP proteins in complexes referred to as *nuclear mRNPs*. Before an mRNA can be translated into its encoded protein, it must be exported out of the nucleus into the cytoplasm.

The **nuclear envelope** is a double membrane that separates the nucleus from the cytoplasm (see Figure 9-32). Like the plasma membrane surrounding cells, each nuclear membrane consists of a water-impermeable phospholipid bilayer and multiple associated proteins. mRNPs and other macromolecules including tRNAs and ribosomal subunits traverse the nuclear envelope through *nuclear pores*. This section will focus on the export of mRNPs through the nuclear pore and the mechanisms that allow some level of regulation of this step. Transport of other cargoes across the nuclear pore is discussed in Chapter 13.

Macromolecules Exit and Enter the Nucleus Through Nuclear Pore Complexes

Nuclear pore complexes (NPCs) are large, symmetrical structures composed of multiple copies of approximately 30 different proteins called **nucleoporins**. Embedded in the nuclear envelope, NPCs are cylindrical in shape with a diameter of ~30 nm (Figure 8-20a). A special class of nucleoporins called **FG-nucleoporins** line the central channel through the NPC. FG-nucleoporins form a semi-permeable barrier that allows small molecules to diffuse freely, but restricts the passage of larger molecules. The FG-nucleoporin globular domain anchors the protein in the NPC scaffold. From these anchors, long random-coil stretches extend into the channel. These extensions are composed of hydrophilic amino acid sequences punctuated by hydrophobic *FG-repeats*, short sequences rich in hydrophobic phenylalanine (F) and glycine (G). These FG-repeat domains form a cloud of polypeptide chains in the central channel and extending into the nucleoplasm and cytoplasm, effectively limiting the free diffusion of macromolecules across the channel. Water, ions, metabolites, and small globular proteins up to ~40–60 kDa can diffuse through the cloud of FG-repeat domains. However, the FG-domains in the central channel form a barrier restricting the diffusion of larger macromolecules between the cytoplasm and nucleus.

Proteins and RNPs larger than ~40–60 kDa must be selectively transported across the nuclear envelope with the assistance of soluble transporter proteins that bind them and also interact reversibly with the FG-repeats of FG-nucleoporins. As a consequence of these reversible interactions with FG-domains, the transporter and its stably bound cargo can be passed from FG-domain to FG-domain, allowing them both to diffuse down a concentration gradient from the nucleus to the cytoplasm.

mRNPs are transported through the NPC by the *mRNP exporter*, a heterodimer consisting of a large subunit, called *nuclear export factor 1* (NXF1), and a small subunit, *nuclear export transporter 1* (NXT1) (Figure 8-20b). NXF1 binds nuclear mRNPs through associations with both RNA and other proteins in the mRNP complex. One of the most important of these is REF (*RNA export factor*), a component of the exon-junction complexes discussed earlier, which is bound approximately 20 nucleotides 5' to each exon-exon junction (see Figure 8-21). The NXF1/NXT1 mRNP exporter also associates with SR proteins bound to exonic splicing

FIGURE 8-20 Model of transporter passage through an NPC.

(a) Diagram of NPC structure. The nuclear envelope lipid bilayers are represented in green. Transmembrane proteins represented in red form a luminal ring around which the nuclear envelope membrane folds to form the inner and outer nuclear membranes. Transmembrane domains of these proteins are connected to globular domains on the inside of the pore to which the other nucleoporins bind, forming the core scaffold. The globular domains of the FG-nucleoporins are shown

in purple. The FG-domains of FG-nucleoporins (tan worms) have an extended, random-coil conformation that forms a molecular cloud of continuously moving random-coil polypeptide. (b) Nuclear transporters (NXF1/NXT1) have hydrophobic regions on their surface that bind reversibly to the FG-domains in the FG-nucleoporins. As a consequence, they can penetrate the molecular cloud in the NPC central channel and diffuse in and out of the nucleus. [Adapted from D. Grünwald, R. H. Singer, and M. Rout, 2011, *Nature* 475:333.]

enhancers. Thus SR proteins associated with exons function to direct both the splicing of pre-mRNAs and the export of fully processed mRNAs through NPCs to the cytoplasm. mRNPs are probably bound along their length by multiple NXF1/NXT1 mRNP exporters, which interact with the FG-domains of FG-nucleoporins to facilitate export of mRNPs through the NPC central channel (Figure 8-20b).

Protein filaments extend from the core scaffold into the nucleoplasm forming a “nuclear basket” (see Figure 8-20a). Protein filaments also extend into the cytoplasm. These filaments assist in mRNP export. Gle2, an adapter protein that reversibly binds both NXF1 and a nucleoporin in the nuclear basket, brings nuclear mRNPs to the pore in preparation for export. A nucleoporin in the cytoplasmic filaments of the NPC

FIGURE 8-21 Remodeling of mRNPs during nuclear export. Some mRNP proteins (rectangles) dissociate from nuclear mRNP complexes before export through an NPC. Some (ovals) are exported through the NPC associated with the mRNP but dissociate in the cytoplasm and are shuttled back into the nucleus through an NPC. In the cytoplasm, translation initiation factor eIF4E replaces CBC bound to the 5' cap and PABPI replaces PABPII.

binds an RNA helicase (Dbp5) that functions in the dissociation of NXF1/NXT1 and other hnRNP proteins from the mRNP as it reaches the cytoplasm.

In a process called *mRNP remodeling*, the proteins associated with an mRNA in the nuclear mRNP complex are exchanged for a different set of proteins as the mRNP is transported through the NPC (Figure 8-21). Some nuclear mRNP proteins dissociate early in transport, remaining in the nucleus to bind to newly synthesized nascent pre-mRNA. Other nuclear mRNP proteins remain with the mRNP complex as it traverses the pore and do not dissociate from the mRNP until the complex reaches the cytoplasm. Proteins in this category include the NXF1/NXT1 mRNP exporter, cap-binding complex (CBC) bound to the 5' cap, and PABPII bound to the poly(A) tail. They dissociate from the mRNP on the cytoplasmic side of the NPC through the action of the Dbp5 RNA helicase that associates with cytoplasmic NPC filaments, as discussed above. These proteins are then imported back into the nucleus as discussed for other nuclear proteins in Chapter 13, where they can function in the export of another mRNP. In the cytoplasm, the cap-binding translation initiation factor eIF4E replaces CBC bound to the 5' cap of nuclear mRNPs (Figure 4-24). In vertebrates, the nuclear poly(A)-binding protein PABPII is replaced with the cytoplasmic poly(A)-binding protein PABPI (so named because it was discovered before PABPII). Only a single PABP is found in budding yeast, in both the nucleus and the cytoplasm.

Yeast SR Protein Studies of *S. cerevisiae* indicate that the direction of mRNP export from the nucleus into the cytoplasm is controlled by phosphorylation and dephosphorylation of mRNP adapter proteins such as REF that assist in the binding of the NXF1/NXT1 exporter to mRNPs. In one case, a yeast SR protein (Npl3) functions as an adapter protein that promotes the binding of the yeast mRNP exporter (Figure 8-22). The SR protein initially binds to nascent pre-mRNA in its phosphorylated form. When 3' cleavage and polyadenylation are completed, the adapter protein is dephosphorylated by a specific nuclear protein phosphatase essential for mRNP export. Only the dephosphorylated adapter protein can bind the mRNP exporter, thereby coupling mRNP export to correct polyadenylation. This is one form of mRNA "quality control." If the nascent mRNP is not correctly processed, it is not recognized by the phosphatase that dephosphorylates Npl3. Consequently, it is not bound by the mRNA exporter and not exported from the nucleus. Instead it is degraded by exosomes, the multiprotein complexes that degrade unprotected RNAs in the nucleus and cytoplasm (see Figure 8-1).

Following export to the cytoplasm, the Npl3 SR protein is phosphorylated by a specific cytoplasmic protein kinase. This causes it to dissociate from the mRNP, along with the mRNP exporter. In this way, dephosphorylation of adapter mRNP proteins in the nucleus once RNA processing is complete and their phosphorylation and resulting dissociation in the cytoplasm results in a higher concentration of mRNP exporter-mRNP complexes in the nucleus, where they form, and a lower concentration of these complexes in the cyto-

plasm, where they dissociate. As a result, the direction of mRNP export may be driven by simple diffusion down a concentration gradient of the transport-competent mRNP exporter-mRNP complex across the NPC, from high in the nucleus to low in the cytoplasm.

Nuclear Export of Balbiani Ring mRNPs The larval salivary glands of the insect *Chironomus tentans* provide a good model system for electron microscopy studies of the formation of hnRNPs and their export through NPCs. In these larvae, genes in large chromosomal puffs called Balbiani rings are abundantly transcribed into nascent pre-mRNAs that associate with hnRNP proteins and are processed into coiled mRNPs with a final mRNA length of ~75 kb (Figure 8-23a, b). These giant mRNAs encode large glue proteins that adhere the developing larvae to a leaf. After processing of the pre-mRNA in Balbiani ring hnRNPs, the resulting mRNPs move through nuclear pores to the cytoplasm. Electron micrographs of sections of these cells show mRNPs that appear to uncoil during their passage through nuclear pores and then bind to ribosomes as they enter the cytoplasm. This uncoiling is probably a consequence of the remodeling of mRNPs as the result of phosphorylation of mRNP proteins by cytoplasmic kinases and the action of the RNA helicase associated with NPC cytoplasmic filaments, as discussed in the previous section. The observation that mRNPs become associated with ribosomes during transport indicates that the 5' end leads the way through the nuclear pore complex. Detailed electron microscopic studies of the transport of Balbiani ring mRNPs through nuclear pore complexes led to the model depicted in Figure 8-23c.

Pre-mRNAs in Spliceosomes Are Not Exported from the Nucleus

It is critical that only fully processed mature mRNAs be exported from the nucleus because translation of incompletely processed pre-mRNAs containing introns would produce defective proteins that might interfere with the functioning of the cell. To prevent this, pre-mRNAs associated with snRNPs in spliceosomes usually are prevented from being transported to the cytoplasm.

In one type of experiment demonstrating this restriction, a gene encoding a pre-mRNA with a single intron that normally is spliced out was mutated to introduce deviations from the consensus splice-site sequences. Mutation of either the 5' or the 3' invariant splice-site bases at the ends of the intron resulted in pre-mRNAs that were bound by snRNPs to form spliceosomes; however, RNA splicing was blocked, and the pre-mRNA was retained in the nucleus. In contrast, mutation of *both* the 5' and 3' splice sites in the same pre-mRNA resulted in export of the unspliced pre-mRNA, although less efficiently than for the spliced mRNA. When both splice sites were mutated, the pre-mRNAs were not efficiently bound by snRNPs, and, consequently, their export was not blocked.

FIGURE 8-22 Reversible phosphorylation and direction of mRNA nuclear export. Step **1**: The yeast SR protein Npl3 binds nascent pre-mRNAs in its phosphorylated form. Step **2**: When polyadenylation has occurred successfully, the Glc7 nuclear phosphatase essential for mRNA export dephosphorylates Npl3, promoting the binding of the yeast mRNA exporter, NXF1/NXT1. Step **3**: The mRNA exporter allows diffusion of the mRNP complex through the central channel of the nuclear pore complex (NPC). Step **4**: The cytoplasmic protein kinase

Sky1 phosphorylates Npl3 in the cytoplasm, causing **5** dissociation of the mRNA exporter and phosphorylated Npl3, probably through the action of an RNA helicase associated with NPC cytoplasmic filaments. **6** The mRNA transporter and phosphorylated Npl3 are transported back into the nucleus through NPCs. **7** Transported mRNA is available for translation in the cytoplasm. [From E. Izaurralde, 2004, *Nat. Struct. Mol. Biol.* **11**:210–212. See W. Gilbert and C. Guthrie, 2004, *Mol. Cell* **13**:201–212.]

Recent studies in yeast have shown that a nuclear protein that associates with a nucleoporin in the NPC nuclear basket is required to retain pre-mRNAs associated with snRNPs in the nucleus. If either this protein or the nucleoporin to which it binds is deleted, unspliced pre-mRNAs are exported.

 Many cases of thalassemia, an inherited disease that results in abnormally low levels of globin proteins, are due to mutations in globin-gene splice sites that decrease the efficiency of splicing but do not prevent association of the pre-mRNA with snRNPs. The resulting unspliced globin pre-mRNAs are retained in reticulocyte nuclei and are rapidly degraded. ■

HIV Rev Protein Regulates the Transport of Unspliced Viral mRNAs

As discussed earlier, transport of mRNPs containing mature, functional mRNAs from the nucleus to the cytoplasm entails a complex mechanism that is crucial to gene expression (see Figures 8-21, 8-22, and 8-23). Regulation of this transport theoretically could provide another means of gene control, although it appears to be relatively rare. Indeed, the only known examples of regulated mRNA export occur during the cellular response to conditions (e.g., heat shock) that cause protein denaturation or during viral infection when

FIGURE 8-23 Formation of heterogeneous ribonucleoprotein particles (hnRNPs) and export of mRNPs from the nucleus.

(a) Model of a single chromatin transcription loop and assembly of Balbiani ring (BR) mRNP in *Chironomus tentans*. Nascent RNA transcripts produced from the template DNA rapidly associate with proteins, forming hnRNPs. The gradual increase in size of the hnRNPs reflects the increasing length of RNA transcripts at greater distances from the transcription start site. The model was reconstructed from electron micrographs of serial thin sections of salivary gland cells. (b) Schematic diagram of the biogenesis of hnRNPs. Following processing of the pre-mRNA, the resulting ribonucleoprotein particle is referred to as an mRNP. (c) Model for the transport of BR mRNPs through the nuclear pore complex (NPC) based on electron microscopic studies. Note that the curved mRNPs appear to uncoil as they pass through nuclear pores. As the mRNA enters the cytoplasm, it rapidly associates with ribosomes, indicating that the 5' end passes through the NPC first. (Part (a) from C. Ericsson et al., 1989, *Cell* **56**:631; courtesy of B. Daneholt. Parts (b) and (c) adapted from B. Daneholt, 1997, *Cell* **88**:585. See also B. Daneholt, 2001, *Proc. Nat'l. Acad. Sci. USA* **98**:7012.)

virus-induced alterations in nuclear transport maximize viral replication. Here we describe the regulation of mRNP export mediated by a protein encoded by human immunodeficiency virus (HIV).

A retrovirus, HIV integrates a DNA copy of its RNA genome into the host-cell DNA (see Figure 4-49). The integrated viral DNA, or provirus, contains a single transcription unit, which is transcribed into a single primary transcript by cellular RNA polymerase II. The HIV transcript can be spliced in alternative ways to yield three classes of mRNAs: a 9-kb unspliced mRNA; ~4-kb mRNAs formed by removal of one intron; and ~2-kb mRNAs formed by removal of two or more introns (Figure 8-24). After their synthesis in the host-cell nucleus, all three classes of HIV mRNAs are transported to the cytoplasm and translated into viral proteins; some of the 9-kb unspliced RNA is used as the viral genome in progeny virions that bud from the cell surface.

Since the 9-kb and 4-kb HIV mRNAs contain splice sites, they can be viewed as incompletely spliced mRNAs. As discussed earlier, association of such incompletely spliced mRNAs with snRNPs in spliceosomes normally blocks their export from the nucleus. Thus HIV, as well as other retroviruses, must

have some mechanism for overcoming this block, permitting export of the longer viral mRNAs. Some retroviruses have evolved a sequence called the *constitutive transport element (CTE)*, which binds to the NXF1/NXT1 mRNP exporter with high affinity, thereby permitting export of unspliced retroviral RNA into the cytoplasm. HIV solved the problem differently.

Studies with HIV mutants showed that transport of unspliced 9-kb and singly spliced 4-kb viral mRNAs from the nucleus to the cytoplasm requires the virus-encoded Rev protein. Subsequent biochemical experiments demonstrated that Rev binds to a specific Rev-response element (RRE) present in HIV RNA. In cells infected with HIV mutants lacking the RRE, unspliced and singly spliced viral mRNAs remain in the nucleus, demonstrating that the RRE is required for Rev-mediated stimulation of nuclear export. Early in an infection, before any Rev protein is synthesized, only the multiply spliced 2-kb mRNAs can be exported. One of these 2-kb mRNAs encodes Rev, which contains a leucine-rich nuclear export signal that interacts with transporter Exportin1. As discussed in Chapter 13, translation and nuclear import of Rev results in export of the larger unspliced and singly spliced HIV mRNAs through the nuclear pore complex.

FIGURE 8-24 Transport of HIV mRNAs from the nucleus to the cytoplasm. The HIV genome, which contains several coding regions, is transcribed into a single 9-kb primary transcript. Several ~4-kb mRNAs result from alternative splicing out of any one of several introns (dashed lines) and several ~2-kb mRNAs from splicing out of two or more alternative introns. After transport to the cytoplasm, the various

RNA species are translated into different viral proteins. Rev protein, encoded by a 2-kb mRNA, interacts with the Rev-response element (RRE) in the unspliced and singly spliced mRNAs, stimulating their transport to the cytoplasm. [Adapted from B. R. Cullen and M. H. Malim, 1991, *Trends Biochem. Sci.* 16:346.]

KEY CONCEPTS of Section 8.3

Transport of mRNA Across the Nuclear Envelope

- Most mRNPs are exported from the nucleus by a heterodimeric mRNP exporter that interacts with FG-repeats of FG-nucleoporins (see Figure 8-20). The direction of transport (nucleus→cytoplasm) may result from dissociation of the exporter-mRNP complex in the cytoplasm by phosphorylation of mRNP proteins by cytoplasmic kinases and the action of an RNA helicase associated with cytoplasmic filaments of the nuclear pore complexes.
- The mRNP exporter binds to most mRNAs cooperatively with SR proteins bound to exons and with REF associated with the exon-junction complexes that bind to mRNAs following RNA splicing, and also binds to additional mRNP proteins.
- Pre-mRNAs bound by a spliceosome normally are not exported from the nucleus, ensuring that only fully processed, functional mRNAs reach the cytoplasm for translation.

8.4 Cytoplasmic Mechanisms of Post-transcriptional Control

Before proceeding, let's quickly review the steps in gene expression at which control is exerted. We saw in the previous chapter that regulation of transcription initiation and tran-

scription elongation in the promoter proximal region are the initial mechanisms for controlling the expression of genes in the gene expression pathway of DNA→RNA→protein. In preceding sections of this chapter, we learned that the expression of protein isoforms is controlled by regulating alternative RNA splicing and cleavage and polyadenylation at alternative poly(A) sites. Although nuclear export of fully and correctly processed mRNPs to the cytoplasm is rarely regulated, the export of improperly processed or aberrantly remodeled pre-mRNPs is prevented, and such abnormal transcripts are degraded by the exosome. However, retroviruses, including HIV, have evolved mechanisms that permit pre-mRNAs that retain splice sites to be exported and translated.

In this section we consider other mechanisms of post-transcriptional control that contribute to regulating the expression of some genes. Most of these mechanisms operate in the cytoplasm, controlling the stability or localization of mRNA or its translation into protein. We begin by discussing two recently discovered and related mechanisms of gene control that provide powerful new techniques for manipulating the expression of specific genes for experimental and therapeutic purposes. These mechanisms are controlled by short, ~22-nucleotide, single-stranded RNAs called **micro RNAs (miRNAs)** and **short interfering (siRNAs)**. Both base-pair with specific target mRNAs, either inhibiting their translation (miRNAs) or causing their degradation (siRNAs). Humans express ~500 miRNAs. Most of these are expressed in specific cell types at particular times during embryogenesis and after birth. Many miRNAs can target more than one

(a) miRNA → translation inhibition

(b) siRNA → RNA cleavage

FIGURE 8-25 Base pairing with target RNAs distinguishes miRNA and siRNA. (a) miRNAs hybridize imperfectly with their target mRNAs, repressing translation of the mRNA. Nucleotides 2 to 7 of an miRNA (highlighted blue) are the most critical for targeting it to a specific

mRNA. (b) siRNA hybridizes perfectly with its target mRNA, causing cleavage of the mRNA at the position indicated by the red arrow, triggering its rapid degradation. [Adapted from P. D. Zamore and B. Haley, 2005, *Science* 309:1519.]

mRNA. Consequently, these newly discovered mechanisms contribute significantly to the regulation of gene expression. siRNAs, involved in the process called RNA interference, are also an important cellular defense against viral infection and excessive transposition by transposons.

Micro RNAs Repress Translation of Specific mRNAs

Micro RNAs (miRNAs) were first discovered during analysis of mutations in the *lin-4* and *let-7* genes of the nematode *C. elegans*, which influence development of the organism. Cloning and analysis of wild-type *lin-4* and *let-7* revealed that they encode not protein products but rather RNAs only 21 and 22 nucleotides long, respectively. The RNAs hybridize to the 3' untranslated regions of specific target mRNAs. For example, the *lin-4* miRNA, which is expressed early in embryogenesis, hybridizes to the 3' untranslated regions of both the *lin-14* and *lin-28* mRNAs in the cytoplasm, thereby repressing their translation by a mechanism discussed below. Expression of *lin-4* miRNA ceases later in development, allowing translation of newly synthesized *lin-14* and *lin-28* mRNAs at that time. Expression of *let-7* miRNA occurs at comparable times during embryogenesis of all bilaterally symmetric animals.

miRNA regulation of translation appears to be widespread in all multicellular plants and animals. In the past few years, small RNAs of 20–26 nucleotides have been isolated, cloned, and sequenced from various tissues of multiple model organisms. Recent estimates suggest the expression of one-third of all human genes is regulated by ~500 human miRNAs isolated from various tissues. The potential for regulation of multiple mRNAs by one miRNA is great because base pairing between the miRNA and the sequence in the 3' ends of mRNAs

that they regulate need not be perfect (Figure 8-25). In fact, considerable experimentation with synthetic miRNAs has shown that complementarity between the six or seven 5' nucleotides of an miRNA and its target mRNA 3' untranslated region are most critical for target mRNA selection.

Most miRNAs are processed from RNA polymerase II transcripts of several hundred to thousands of nucleotides in length called pri (for *primary* transcript)-miRNAs (Figure 8-26). Pri-miRNAs can contain the sequence of one or more miRNAs. miRNAs are also processed out of some excised introns and from 3' untranslated regions of some pre-mRNAs. Within these long transcripts are sequences that fold into hairpin structures of ~70 nucleotides in length with imperfect base pairing in the stem. A nuclear RNase specific for double-stranded RNA called *Drosha* acts with a nuclear double-stranded RNA-binding protein called DGCR8 in humans (Pasha in *Drosophila*) and cleaves the hairpin region out of the long precursor RNA, generating a pre-miRNA. Pre-miRNAs are recognized and bound by a specific nuclear transporter, *Exportin5*, which interacts with the FG-domains of nucleoporins, allowing the complex to diffuse through the inner channel of the nuclear pore complex, as discussed above (see Figure 8-20, and Chapter 13). Once in the cytoplasm, a cytoplasmic double-stranded RNA-specific RNase called *Dicer* acts with a cytoplasmic double-stranded RNA-binding protein called *TRBP* in humans (for *Tar* binding protein; called *Loquacious* in *Drosophila*) to further process the pre-miRNA into a double-stranded miRNA. The double-stranded miRNA is approximately two turns of an A-form RNA helix in length, with strands 21–23 nucleotides long and two unpaired 3'-nucleotides at each end. Finally, one of the two strands is selected for assembly into a mature **RNA-induced silencing complex (RISC)** containing a single-stranded mature miRNA bound by a

FIGURE 8-26 miRNA processing. This diagram shows transcription and processing of the miR-1-1 miRNA. The primary miRNA transcript (pri-miRNA) is transcribed by RNA polymerase II. The nuclear double-stranded RNA-specific endoribonuclease Drosha, with its partner double-stranded RNA-binding protein DGCR8 (Pasha in *Drosophila*), make the initial cleavages in the pri-miRNA, generating a ~70-nucleotide pre-miRNA that is exported to the cytoplasm by nuclear transporter Exportin5. The pre-miRNA is further processed in the cytoplasm to a double-stranded miRNA with a two-base single-stranded 3' end by Dicer in conjunction with the double-stranded RNA-binding protein TRBP (Loquacious in *Drosophila*). Finally, one of the two strands is incorporated into an RISC complex, where it is bound by an Argonaute protein. [Adapted from P. D. Zamore and B. Haley, 2005, *Science* 309:1519.]

multidomain *Argonaute* protein, a member of a protein family with a recognizable conserved sequence. Several Argonaute proteins are expressed in some organisms, especially plants, and are found in distinct RISC complexes with different functions.

The miRNA-RISC complexes associate with target mRNPs by base pairing between the Argonaute-bound mature miRNA and complementary regions in the 3' untranslated regions (3' UTRs) of target mRNAs (see Figure 8-25). Inhibition of target mRNA translation requires the binding of two or more RISC complexes to distinct complementary regions in the target mRNA 3' UTR. It has been suggested that this may allow combinatorial regulation of mRNA translation by separately regulating the transcription of two or more different pri-miRNAs, which are processed to miRNAs that are required in combination to suppress the translation of a specific target mRNA.

The binding of several RISC complexes to an mRNA inhibits translation initiation by a mechanism currently being analyzed. Binding of RISC complexes causes the bound mRNPs to associate with dense cytoplasmic domains many times the size of a ribosome called cytoplasmic RNA-processing bodies, or simply P bodies. P bodies, which will be described in greater detail below, are sites of RNA degradation that contain no ribosomes or translation factors, potentially explaining the inhibition of translation. The association with P bodies may also explain why expression of an miRNA often decreases the stability of a targeted mRNA.

As mentioned earlier, approximately 500 different human miRNAs have been observed, many of them expressed only in specific cell types. Determining the function of these miRNAs is currently a highly active area of research. In one example, a specific miRNA called miR-133 is induced when myoblasts differentiate into muscle cells. miR-133 suppresses the translation of PTB, a regulatory splicing factor that functions similarly to Sxl in *Drosophila* (see Figure 8-16). PTB binds to the 3' splice-site region in the pre-mRNAs of many genes, leading to exon skipping or use of alternative 3' splice sites. When miR-133 is expressed in differentiating myoblasts, the PTB concentration falls without a significant decrease in the concentration of PTB mRNA. As a result, alternative isoforms of multiple proteins important for muscle-cell function are expressed in the differentiated cells.

Other examples of miRNA regulation in various organisms are being discovered at a rapid pace. Knocking out the *dicer* gene eliminates the generation of miRNA in mammals. This causes embryonic death early in mouse development. However, when *dicer* is knocked out only in limb primordia, the influence of miRNA on the development of the nonessential limbs can be observed (Figure 8-27). Although all major cell types differentiate and the fundamental aspects of limb patterning are maintained, development is abnormal—demonstrating the importance of miRNAs in regulating the proper level of translation of multiple mRNAs. Of the ~500 human miRNAs, 53 appear to be unique to primates. It seems likely that new miRNAs arose readily during evolution by the duplication of a pri-miRNA gene followed by mutation

EXPERIMENTAL FIGURE 8-27 miRNA function in limb development. Micrographs comparing normal (left) and Dicer knockout (right) limbs of embryonic development day-13 mouse embryos immunostained for the Gd5 protein, a marker of joint formation. Dicer is knocked out in developing mouse embryos by conditional expression of Cre to induce deletion of the Dicer gene only in these cells (see Figure 5-42). [From B. D. Harfe et al., 2005, *Proc. Nat'l. Acad. Sci. USA* 102:10898.]

of bases encoding the mature miRNA. miRNAs are particularly abundant in plants—more than 1.5 million distinct miRNAs have been characterized in *Arabidopsis thaliana*!

RNA Interference Induces Degradation of Precisely Complementary mRNAs

RNA interference (RNAi) was discovered unexpectedly during attempts to experimentally manipulate the expression of specific genes. Researchers tried to inhibit the expression of a gene in *C. elegans* by microinjecting a single-stranded, complementary RNA that would hybridize to the encoded mRNA and prevent its translation, a method called antisense inhibition. But in control experiments, perfectly base-paired double-stranded RNA a few hundred base pairs long was much more effective at inhibiting expression of the gene than the antisense strand alone (see Figure 5-45). Similar inhibition of gene expression by an introduced double-stranded RNA soon was observed in plants. In each case, the double-stranded RNA induced degradation of all cellular RNAs containing a sequence that was exactly the same as one strand of the double-stranded RNA. Because of the specificity of RNA interference in targeting mRNAs for destruction, it has become a powerful experimental tool for studying gene function.

Subsequent biochemical studies with extracts of *Drosophila* embryos showed that a long double-stranded RNA that mediates interference is initially processed into a double-stranded short interfering RNA (siRNA). The strands in siRNA contain 21–23 nucleotides hybridized to each other so that the two bases at the 3' end of each strand are single-stranded. Further studies revealed that the cytoplasmic double-stranded RNA-specific ribonuclease that cleaves long double-stranded RNA into siRNAs is the same Dicer enzyme involved in processing pre-miRNAs after their nuclear export to the cytoplasm (see Figure 8-26). This discovery led to the realization that RNA interference and miRNA-mediated translational repression are related processes. In both

cases, the mature short single-stranded RNA, either mature siRNA or mature miRNA, is assembled into RISC complexes in which the short RNAs are bound by an Argonaute protein. What distinguishes a RISC complex containing an siRNA from one containing an miRNA is that the siRNA base-pairs extensively with its target RNA and induces its cleavage, whereas a RISC complex associated with an miRNA recognizes its target through imperfect base-pairing and results in inhibition of translation.

The Argonaute protein is responsible for cleavage of target RNA; one domain of the Argonaute protein is homologous to RNase H enzymes that degrade the RNA of an RNA-DNA hybrid (see Figure 6-14). When the 5' end of the short RNA of a RISC complex base-pairs precisely with a target mRNA over a distance of one turn of an RNA helix (10–12 base pairs), this domain of Argonaute cleaves the phosphodiester bond of the target RNA across from nucleotides 10 and 11 of the siRNA (see Figure 8-25). The cleaved RNAs are released and subsequently degraded by cytoplasmic exosomes and 5' exoribonucleases. If base pairing is not perfect, the Argonaute domain does not cleave or release the target mRNA. Instead, if several miRNA-RISC complexes associate with a target mRNA, its translation is inhibited and the mRNA becomes associated with P bodies, where, as mentioned earlier, it is probably degraded by a different and slower mechanism than the degradation pathway initiated by RISC cleavage of a perfectly complementary target RNA.

When double-stranded RNA is introduced into the cytoplasm of eukaryotic cells, it enters the pathway for assembly of siRNAs into a RISC complex because it is recognized by the cytoplasmic Dicer enzyme and TRBP double-stranded RNA-binding protein that process pre-miRNAs (see Figure 8-26). This process of RNA interference is believed to be an ancient cellular defense against certain viruses and mobile genetic elements in both plants and animals. Plants with mutations in the genes encoding Dicer and RISC proteins exhibit increased sensitivity to infection by RNA viruses and increased movement of transposons within their genomes. The double-stranded RNA intermediates generated during replication of RNA viruses are thought to be recognized by the Dicer ribonuclease, inducing an RNAi response that ultimately degrades viral mRNAs. During transposition, transposons are inserted into cellular genes in a random orientation, and their transcription from different promoters produces complementary RNAs that can hybridize with each other, initiating the RNAi system that then interferes with the expression of transposon proteins required for additional transpositions.

In plants and *C. elegans* the RNAi response can be induced in all cells of the organism by introduction of double-stranded RNA into just a few cells. Such organism-wide induction requires production of a protein that is homologous to the RNA replicases of RNA viruses. It has been revealed that double-stranded siRNAs are replicated and then transferred to other cells in these organisms. In plants, transfer of siRNAs might occur through plasmodesmata, the cytoplasmic connections between plant cells that traverse the cell walls between them (see Figure 20-38). Organism-wide induction

of RNA interference does not occur in *Drosophila* or mammals, presumably because their genomes do not encode RNA replicase homologs.

In mammalian cells, the introduction of long RNA-RNA duplex molecules into the cytoplasm results in the generalized inhibition of protein synthesis via the PKR pathway, discussed further below. This greatly limits the use of long double-stranded RNAs to experimentally induce an RNAi response against a specific targeted mRNA. Fortunately, researchers discovered that one strand of double-stranded siRNAs 21–23 nucleotides in length with two-base 3' single-stranded regions leads to the generation of mature siRNA RISC complexes without inducing the generalized inhibition of protein synthesis. This has allowed researchers to use synthetic double-stranded siRNAs to “knock down” the expression of specific genes in human cells as well as in other mammals. This method of siRNA knockdown is now widely used in studies of diverse processes, including the RNAi pathway itself.

Cytoplasmic Polyadenylation Promotes Translation of Some mRNAs

In addition to repression of translation by miRNAs, other protein-mediated translational controls help regulate expression of some genes. Regulatory sequences, or elements, in mRNAs that interact with specific proteins to control translation generally are present in the untranslated region (UTR) at the 3' or 5' end of an mRNA. Here we discuss a type of protein-mediated translational control involving 3' regulatory elements. A different mechanism involving RNA-binding proteins that interact with 5' regulatory elements is discussed later.

Translation of many eukaryotic mRNAs is regulated by sequence-specific RNA-binding proteins that bind cooperatively to neighboring sites in 3' UTRs. This allows them to function in a combinatorial manner, similar to the cooperative binding of transcription factors to regulatory sites in an enhancer or promoter region. In most cases studied, translation is repressed by protein binding to 3' regulatory elements and regulation results from derepression at the appropriate time or place in a cell or developing embryo. The mechanism of such repression is best understood for mRNAs that must undergo *cytoplasmic polyadenylation* before they can be translated.

Cytoplasmic polyadenylation is a critical aspect of gene expression in the early embryo of animals. The egg cells (oocytes) of multicellular animals contain many mRNAs, encoding numerous different proteins that are not translated until after the egg is fertilized by a sperm cell. Some of these “stored” mRNAs have a short poly(A) tail, consisting of only ~20–40 A residues, to which just a few molecules of cytoplasmic poly(A)-binding protein (PABPI) can bind. As discussed in Chapter 4, multiple PABPI molecules bound to the long poly(A) tail of an mRNA interact with the eIF4G initiation factor, thereby stabilizing the interaction of the mRNA 5' cap with eIF4E, which is required for translation initiation (see Figure 4-24). Because this stabilization cannot occur with mRNAs that have short poly(A) tails, such

mRNAs stored in oocytes are not translated efficiently. At the appropriate time during oocyte maturation or after fertilization of an egg cell, usually in response to an external signal, approximately 150 A residues are added to the short poly(A) tails on these mRNAs in the cytoplasm, stimulating their translation.

Studies with mRNAs stored in *Xenopus* oocytes have helped elucidate the mechanism of this type of translational control. Experiments in which short-tailed mRNAs are injected into oocytes have shown that two sequences in their 3' UTR are required for their polyadenylation in the cytoplasm: the AAUAAA poly(A) signal that is also required for the nuclear polyadenylation of pre-mRNAs, and one or more copies of an upstream U-rich *cytoplasmic polyadenylation element* (CPE). This regulatory element is bound by a highly conserved *CPE-binding protein* (CPEB) that contains an RRM domain and a zinc-finger domain.

According to the current model, in the absence of a stimulatory signal, CPEB bound to the U-rich CPE interacts with the protein Maskin, which in turn binds to eIF4E associated with the mRNA 5' cap (Figure 8-28, *left*). As a result, eIF4E cannot interact with other initiation factors and the 40S ribosomal subunit, so translation initiation is blocked. During oocyte maturation, a specific CPEB serine is phosphorylated, causing Maskin to dissociate from the complex. This allows cytoplasmic forms of the cleavage and polyadenylation specificity factor (CPSF) and poly(A) polymerase to bind to the mRNA cooperatively with CPEB. Once the poly(A) polymerase catalyzes the addition of A residues, PABPI can bind to the lengthened poly(A) tail, leading to the stabilized interaction of all the factors needed to initiate translation (Figure 8-28, *right*; see also Figure 4-24). In the case of *Xenopus* oocyte maturation, the protein kinase that phosphorylates CPEB is activated in response to the hormone progesterone. Thus timing of the translation of stored mRNAs encoding proteins needed for oocyte maturation is regulated by this external signal.

Considerable evidence indicates that a similar mechanism of translational control plays a role in learning and memory. In the central nervous system, the axons from a thousand or so neurons can make connections (synapses) with the dendrites of a single postsynaptic neuron (Figure 22-23). When one of these axons is stimulated, the postsynaptic neuron “remembers” which one of these thousands of synapses was stimulated. The next time that synapse is stimulated, the strength of the response triggered in the postsynaptic cell differs from the first time. This change in response has been shown to result largely from the translational activation of mRNAs stored in the region of the synapse, leading to the local synthesis of new proteins that increase the size and alter the neurophysiological characteristics of the synapse. The finding that CPEB is present in neuronal dendrites has led to the proposal that cytoplasmic polyadenylation stimulates translation of specific mRNAs in dendrites, much as it does in oocytes. In this case, presumably, synaptic activity (rather than a hormone) is the signal that induces phosphorylation of CPEB and subsequent activation of translation.

FIGURE 8-28 Model for control of cytoplasmic polyadenylation and translation initiation. (Left) In immature oocytes, mRNAs containing the U-rich cytoplasmic polyadenylation element (CPE) have short poly(A) tails. CPE-binding protein (CPEB) mediates repression of translation through the interactions depicted, which prevent assembly of an initiation complex at the 5' end of the mRNA. (Right) Hormone stimulation of oocytes activates a protein kinase that phosphorylates CPEB, causing it to release Maskin. The cleavage and polyadenylation

specificity factor (CPSF) then binds to the poly(A) site, interacting with both bound CPEB and the cytoplasmic form of poly(A) polymerase (PAP). After the poly(A) tail is lengthened, multiple copies of the cytoplasmic poly(A)-binding protein I (PABPI) can bind to it and interact with eIF4G, which functions with other initiation factors to bind the 40S ribosome subunit and initiate translation. [Adapted from R. Mendez and J. D. Richter, 2001, *Nature Rev. Mol. Cell Biol.* 2:521.]

Degradation of mRNAs in the Cytoplasm Occurs by Several Mechanisms

The concentration of an mRNA is a function of both its rate of synthesis and its rate of degradation. For this reason, if two genes are transcribed at the same rate, the steady-state concentration of the corresponding mRNA that is more stable will be higher than the concentration of the other. The stability of an mRNA also determines how rapidly synthesis of the encoded protein can be shut down. For a stable mRNA, synthesis of the encoded protein persists long after transcription of the gene is repressed. Most bacterial mRNAs are unstable, decaying exponentially with a typical half-life of a few minutes. For this reason, a bacterial cell can rapidly adjust the synthesis of proteins to accommodate changes in the cellular environment. Most cells in multicellular organisms, on the other hand, exist in a fairly constant environment and carry out a specific set of functions over periods of days to months or even the lifetime of the organism (nerve cells, for example). Accordingly, most mRNAs of higher eukaryotes have half-lives of many hours.

However, some proteins in eukaryotic cells are required only for short periods and must be expressed in bursts. For example, as discussed in the chapter introduction, certain signaling molecules called **cytokines**, which are involved in the immune response of mammals, are synthesized and secreted in short bursts (see Chapter 23). Similarly, many of the transcription factors that regulate the onset of the S phase of the cell cycle, such as c-Fos and c-Jun, are synthesized for brief periods only (Chapter 19). Expression of such proteins occurs in short bursts because transcription of their genes can be rapidly turned on and off, and their mRNAs have unusually short half-lives, on the order of 30 minutes or less.

Cytoplasmic mRNAs are degraded by one of the three pathways shown in Figure 8-29. For most mRNAs, the *deadenylation-dependent pathway* is followed: the length of the poly(A) tail gradually decreases with time through the action of a deadenylating nuclease. When it is shortened sufficiently, PABPI molecules can no longer bind and stabilize the interaction of the 5' cap and translation initiation factors (see Figure 4-24). The exposed cap then is removed by a decapping enzyme (Dcp1/Dcp2 in *S. cerevisiae*), and the unprotected mRNA is degraded by a 5'→3' exonuclease (Xrn1 in *S. cerevisiae*). Removal of the poly(A) tail also makes mRNAs susceptible to degradation by cytoplasmic exosomes containing 3'→5' exonucleases. The 5'→3' exonucleases predominate in yeast, and the 3'→5' exosome predominates in mammalian cells. The decapping enzymes and 5'→3' exonuclease are concentrated in the P bodies, regions of the cytoplasm of unusually high density.

Some mRNAs are degraded primarily by a *deadenylation-independent decapping pathway* (see Figure 8-29). This is because certain sequences at the 5' end of an mRNA seem to make the cap sensitive to the decapping enzyme. For these mRNAs, the rate at which they are decapped controls the rate at which they are degraded because once the 5' cap is removed, the RNA is rapidly hydrolyzed by the 5'→3' exonuclease.

The rate of mRNA deadenylation varies inversely with the frequency of translation initiation for an mRNA: the higher the frequency of initiation, the slower the rate of deadenylation. This relation probably is due to the reciprocal interactions between translation initiation factors bound at the 5' cap and PABPI bound to the poly(A) tail. For an mRNA that is translated at a high rate, initiation factors are bound to the cap much of the time, stabilizing the binding of PABPI and thereby protecting the poly(A) tail from the deadenylation exonuclease.

FIGURE 8-29 Pathways for degradation of eukaryotic mRNAs.

In the deadenylation-dependent (*middle*) pathways, the poly(A) tail is progressively shortened by a deadenylase (orange) until it reaches a length of 20 or fewer A residues, at which point the interaction with PABPI is destabilized, leading to weakened interactions between the 5' cap and translation-initiation factors. The deadenylated mRNA then

may either (1) be decapped and degraded by a 5' → 3' exonuclease or (2) be degraded by a 3' → 5' exonuclease in cytoplasmic exosomes. Some mRNAs (*right*) are cleaved internally by an endonuclease and the fragments degraded by an exosome. Other mRNAs (*left*) are decapped before they are deadenylated and then degraded by a 5' → 3' exonuclease. [Adapted from M. Tucker and R. Parker, 2000, *Ann. Rev. Biochem.* **69**:571.]

Many short-lived mRNAs in mammalian cells contain multiple, sometimes overlapping copies of the sequence AUUUA in their 3' untranslated region. Specific RNA-binding proteins have been found that both bind to these 3' AU-rich sequences and also interact with a deadenylating enzyme and with the exosome. This causes rapid deadenylation and subsequent 3' → 5' degradation of these mRNAs. In this mechanism, the rate of mRNA degradation is uncoupled from the frequency of translation. Thus mRNAs containing the AUUUA sequence can be translated at high frequency yet also be degraded rapidly, allowing the encoded proteins to be expressed in short bursts.

As shown in Figure 8-29, some mRNAs are degraded by an *endonucleolytic pathway* that does not involve decapping or significant deadenylation. One example of this type of pathway is the RNAi pathway discussed above (see Figure 8-25). Each siRNA-RISC complex can degrade thousands of targeted RNA molecules. The fragments generated by internal cleavage then are degraded by exonucleases.

P Bodies As mentioned above, P bodies are sites of translational repression of mRNAs bound by miRNA-RISC complexes. They are also the major sites of mRNA degradation in the cytoplasm. These dense regions of cytoplasm contain the decapping enzyme (Dcp1/Dcp2 in yeast), activators of decapping (Dhh, Pat1, Lsm1-7 in yeast), the major 5' → 3' exonuclease (Xrn1), as well as densely associated mRNAs. P bodies are dynamic structures that grow and shrink in size depending on the rate at which mRNPs associate with them, the rate at which mRNAs are degraded, and the rate at which mRNPs exit P bodies and reenter the pool of translated mRNPs. mRNAs whose translation is inhibited by imperfect base-pairing of miRNAs (Figure 8-25) are major components of P-bodies.

Protein Synthesis Can Be Globally Regulated

Like proteins involved in other processes, translation initiation factors and ribosomal proteins can be regulated by post-

translational modifications such as phosphorylation. Such mechanisms affect the translation rate of most mRNAs and hence the overall rate of cellular protein synthesis.

TOR Pathway The TOR pathway was discovered through research into the mechanism of action of rapamycin, an antibiotic produced by a strain of *Streptomyces* bacteria, which is useful for suppressing the immune response in organ transplant patients. The *target of rapamycin* (TOR) was identified by isolating yeast mutants resistant to rapamycin inhibition of cell growth. TOR is a large (~2400 amino acid residue) protein kinase that regulates several cellular processes in yeast cells in response to nutritional status. In multicellular eukaryotes, *metazoan TOR* (mTOR) also responds to multiple signals from cell-surface-signaling proteins to coordinate cell growth with developmental programs as well as nutritional status.

Current understanding of the mTOR pathway is summarized in Figure 8-30. Active mTOR stimulates the overall rate of protein synthesis by phosphorylating two critical proteins that regulate translation directly. mTOR also activates transcription factors that control expression of ribosomal components, tRNAs, and translation factors, further activating protein synthesis and cell growth.

Recall that the first step in translation of a eukaryotic mRNA is binding of the eIF4 initiation complex to the 5' cap via its eIF4E cap-binding subunit (see Figure 4-24). The concentration of active eIF4E is regulated by a small family of homologous *eIF4E-binding proteins* (4E-BPs) that inhibit the interaction of eIF4E with mRNA 5' caps. 4E-BPs are direct targets of mTOR. When phosphorylated by mTOR, 4E-BPs release eIF4E, stimulating translation initiation. mTOR also phosphorylates and activates another protein kinase (S6K) that phosphorylates the small ribosomal subunit protein S6 and probably additional substrates, leading to a further increase in the rate of protein synthesis.

FIGURE 8-30 mTOR pathway. mTOR is an active protein kinase when bound by a complex of Rheb and an associated GTP (lower left). In contrast, mTOR is inactive when bound by a complex of Rheb associated with GDP (lower right). When active, the TSC1/TSC2 Rheb-GTPase activating protein (Rheb-GAP) causes hydrolysis of Rheb-bound GTP to GDP, thereby inactivating mTOR. The TSC1/TSC2 Rheb-GAP is activated (arrows) by phosphorylation by AMP kinase (AMPK) when cellular energy charge is low and by other cellular stress responses. Signal-transduction pathways activated by cell-surface growth factor receptors lead to phosphorylation of inactivating sites on TSC1/TSC2, inhibiting its GAP activity. Consequently, they leave a higher fraction of cellular Rheb in the GTP conformation that activates

mTOR protein kinase activity. Low nutrient concentration also regulates Rheb GTPase activity, by a mechanism that does not require TSC1/TSC2. Active mTOR phosphorylates 4E-BP, causing it to release eIF4E, stimulating translation initiation. It also phosphorylates and activates S6 kinase (S6K), which in turn phosphorylates ribosomal proteins, stimulating translation. Activated mTOR also activates transcription factors for RNA polymerases I, II, and III, leading to synthesis and assembly of ribosomes, tRNAs, and translation factors. In the absence of mTOR activity, all of these processes are inhibited. In contrast, activated mTOR inhibits macroautophagy, which is stimulated in cells with inactive mTOR. [Adapted from S. Wullschlegel et al., 2006, *Cell* 124:471.]

Translation of a specific subset of mRNAs that have a string of pyrimidines in their 5' untranslated regions (called TOP mRNAs for *tract of oligopyrimidine*) is stimulated particularly strongly by mTOR. The TOP mRNAs encode ribosomal proteins and translation elongation factors. mTOR also activates the RNA polymerase I transcription factor TIF-1A, stimulating transcription of the large rRNA precursor (see Figure 7-52).

mTOR activates transcription by RNA polymerase III as well, by phosphorylating and thereby activating protein kinases that phosphorylate MAF1, a protein inhibitor of RNA polymerase III transcription. MAF1 phosphorylation causes it to be exported from the nucleus, relieving repression of RNA polymerase III transcription. When mTOR activity falls, MAF1 in the cytoplasm is rapidly dephosphorylated and imported into the nucleus where it represses transcription by RNA polymerase III.

In addition, mTOR activates two RNA polymerase II activators that stimulate transcription of ribosomal protein and

translation factor genes. Finally, mTOR stimulates processing of the rRNA precursor (Section 8.5). As a consequence of phosphorylation of these several mTOR substrates, the synthesis and assembly of ribosomes as well as the synthesis of translation factors and tRNAs are greatly increased. Alternatively, when mTOR kinase activity is inhibited, these substrates become dephosphorylated, greatly decreasing the rate of protein synthesis and the production of ribosomes, translation factors, and tRNAs, thus halting cell growth.

mTOR activity is regulated by a monomeric small G protein in the Ras protein family called Rheb. Like other small G proteins, Rheb is in its active conformation when it is bound to GTP. Rheb-GTP binds the mTOR complex, stimulating mTOR kinase activity, probably by inducing a conformation change in its kinase domain. Rheb is in turn regulated by a heterodimer composed of subunits TSC1 and TSC2, named for their involvement in the medical syndrome tuberous sclerosis complex, as discussed below. In the active conformation,

the TSC1/TSC2 heterodimer functions as a GTPase activating protein for Rheb (Rheb-GAP), causing hydrolysis of the Rheb-bound GTP to GDP. This converts Rheb to its GDP-bound conformation, which binds to the mTOR complex and inhibits its kinase activity. Finally, the activity of the TSC1/TSC2 Rheb-GAP is regulated by several inputs, allowing the cell to integrate different cellular signaling pathways to control the overall rate of protein synthesis. Signaling from cell-surface growth factor receptors leads to phosphorylation of TSC1/TSC2 at inhibitory sites, causing an increase in Rheb-GTP and activation of mTOR kinase activity. This type of regulation through cell-surface receptors links the control of cell growth to developmental processes controlled by cell-cell interactions.

mTOR activity also is regulated in response to nutritional status. When energy from nutrients is not sufficient for cell growth, the resulting fall in the ratio of ATP to AMP concentrations is detected by AMP kinase (AMPK). The activated AMP kinase phosphorylates TSC1/TSC2 at activating sites, stimulating its Rheb-GAP activity and consequently inhibiting mTOR kinase activity and the global rate of translation. Hypoxia and other cellular stresses also activate the TSC1/TSC2 Rheb-GAP. Finally, the concentration of nutrients in the extracellular space also regulates Rheb, by an unknown mechanism that does not require the TSC1/TSC2 complex.

In addition to regulating the global rate of cellular protein synthesis and the production of ribosomes, tRNAs, and translation factors, mTOR regulates at least one other process involved in the response to low levels of nutrients: macroautophagy (or simply **autophagy**). Starved cells degrade cytoplasmic constituents, including whole organelles, to supply energy and precursors for essential cellular processes. During this process a large, double-membrane structure engulfs a region of cytoplasm to form an autophagosome, which then fuses with a lysosome where the entrapped proteins, lipids, and other macromolecules are degraded, completing the process of macroautophagy. Activated mTOR inhibits macroautophagy in growing cells when nutrients are plentiful. Macroautophagy is stimulated when mTOR activity falls in nutrient-deprived cells.

Genes encoding components of the mTOR pathway are mutated in many human cancers, resulting in cell growth in the absence of normal growth signals. TSC1 and TSC2 (see Figure 8-30) were initially identified because one or the other of the proteins is mutant in a rare human genetic syndrome: tuberous sclerosis complex. Patients with this disorder develop benign tumors in multiple tissues. The disease results because inactivation of either TSC1 or TSC2 eliminates the Rheb-GAP activity of the TSC1/TSC2 heterodimer, resulting in an abnormally high and unregulated level of Rheb-GTP and the resulting high, unregulated activity of mTOR. Mutations in components of cell-surface receptor signal-transduction pathways that lead to inhibition of TSC1/TSC2 Rheb-GAP activity are also common in human tumors and contribute to cell growth and replication in the absence of normal signals for growth and proliferation.

High mTOR protein kinase activity in tumors correlates with a poor clinical prognosis. Consequently, mTOR inhibitors are currently in clinical trials to test their effectiveness for treating cancers in conjunction with other modes of therapy. Rapamycin and other structurally related mTOR inhibitors are potent suppressors of the immune response because they inhibit activation and replication of T lymphocytes in response to foreign antigens (Chapter 23). Several viruses encode proteins that activate mTOR early after viral infection. The resulting stimulation of translation has an obvious selective advantage for these cellular parasites. ■

eIF2 Kinases eIF2 kinases also regulate the global rate of cellular protein synthesis. Figure 4-24 summarizes the steps in translation initiation. Translation initiation factor eIF2 brings the charged initiator tRNA to the small ribosome subunit P site. eIF2 is a **trimeric G protein** and consequently exists in either a GTP-bound or a GDP-bound conformation. Only the GTP-bound form of eIF2 is able to bind the charged initiator tRNA and associate with the small ribosomal subunit. The small subunit with bound initiation factors and charged initiator tRNA then interacts with the eIF4 complex bound to the 5' cap of an mRNA via its eIF4E subunit. The small ribosomal subunit then scans down the mRNA in the 3' direction until it reaches an AUG initiation codon that can base-pair with the initiator tRNA in its P site. When this occurs, the GTP bound by eIF2 is hydrolyzed to GDP and the resulting eIF2-GDP complex is released. GTP hydrolysis results in an irreversible “proofreading” step that prepares the small ribosomal subunit to associate with the large subunit only when an initiator tRNA is properly bound in the P site and is properly base-paired with the AUG start codon. Before eIF2 can participate in another round of initiation, its bound GDP must be replaced with a GTP. This process is catalyzed by the translation initiation factor eIF2B, a guanine nucleotide exchange factor (GEF) specific for eIF2.

A mechanism for inhibiting general protein synthesis in stressed cells involves phosphorylation of the eIF2 α subunit at a specific serine. Phosphorylation at this site does not interfere with eIF2 function in protein synthesis directly. Rather, phosphorylated eIF2 has very high affinity for the eIF2 guanine nucleotide exchange factor, eIF2B, which cannot release the phosphorylated eIF2 and consequently is blocked from catalyzing GTP exchange of additional eIF2 factors. Since there is an excess of eIF2 over eIF2B, phosphorylation of a fraction of eIF2 results in inhibition of all the cellular eIF2B. The remaining eIF2 accumulates in its GDP-bound form, which cannot participate in protein synthesis, thereby inhibiting nearly all cellular protein synthesis. However, some mRNAs have 5' regions that allow translation initiation at the low eIF2-GTP concentration that results from eIF2 phosphorylation. These mRNAs include those for chaperone proteins that function to refold cellular proteins denatured as the result of cellular stress, additional proteins that help the cell to cope with stress, and transcription factors that activate transcription of the genes encoding these stress-induced proteins.

Human cells contain four eIF2 kinases that phosphorylate the same inhibitory eIF2 α serine. Each of these is regulated by a different type of cellular stress, inhibiting protein synthesis and allowing cells to divert the large fraction of cellular resources usually devoted to protein synthesis in growing cells for use in responding to the stress.

The GCN2 (general control non-depressible 2) eIF2-kinase is activated by binding uncharged tRNAs. The concentration of uncharged tRNAs increases when cells are starved for amino acids, activating GCN2 eIF2-kinase activity and greatly inhibiting protein synthesis.

PEK (pancreatic eIF2 kinase) is activated when proteins translocated into the endoplasmic reticulum (ER) do not fold properly because of abnormalities in the ER lumen environment. Inducers include abnormal carbohydrate concentration, because this inhibits the glycosylation of many ER proteins, and inactivating mutations in an ER chaperone required for proper folding of many ER proteins (Chapters 13 and 14).

Heme-regulated inhibitor (HRI) is activated in developing red blood cells when the supply of the heme prosthetic group is too low to accommodate the rate of globin protein synthesis. This negative feedback loop lowers the rate of globin protein synthesis until it matches the rate of heme synthesis. HRI is also activated in other types of cells in response to oxidative stress or heat shock.

Finally, protein kinase RNA activated (PKR) is activated by double-stranded RNAs longer than ~ 30 base pairs. Under normal circumstances in mammalian cells, such double-stranded RNAs are produced only during a viral infection. Long regions of double-stranded RNA are generated in replication intermediates of RNA viruses or from hybridization of complementary regions of RNA transcribed from both strands of DNA virus genomes. Inhibition of protein synthesis prevents the production of progeny virions, protecting neighboring cells from infection. Interestingly, adenoviruses evolved a defense against PKR: they express prodigious amounts of an ~ 160 -nucleotide virus-associated (VA) RNA with long double-stranded hairpin regions. VA RNA is transcribed by RNA polymerase III and exported from the nucleus by Exportin5, the exportin for pre-miRNAs (see Figure 8-27). VA RNA binds to PKR with high affinity, inhibiting its protein kinase activity and preventing the inhibition of protein synthesis observed in cells infected with a mutant adenovirus from which the VA gene was deleted.

Sequence-Specific RNA-Binding Proteins Control Specific mRNA Translation

In contrast to global mRNA regulation, mechanisms have also evolved for controlling the translation of certain specific mRNAs. This is usually done by sequence-specific RNA-binding proteins that bind to a particular sequence or RNA structure in the mRNA. When binding is in the 5' untranslated region (5' UTR) of an mRNA, the ribosome's ability to scan to the first initiation codon is blocked, inhibiting translation initiation. Binding in other regions can either promote or inhibit mRNA degradation.

Control of intracellular iron concentration by the *iron response element-binding protein (IRE-BP)* is an elegant example of a single protein that regulates the translation of one mRNA and the degradation of another. Precise regulation of cellular iron ion concentration is critical to the cell. Multiple enzymes and proteins contain Fe^{2+} as a cofactor, such as enzymes of the Krebs cycle (see Figure 12-10) and electron-carrying proteins involved in the generation of ATP by mitochondria and chloroplasts (Chapter 12). On the other hand, excess Fe^{2+} generates free radicals that react with and damage cellular macromolecules. When intracellular iron stores are low, a dual-control system operates to increase the level of cellular iron; when iron is in excess, the system operates to prevent accumulation of toxic levels of free ions.

One component in this system is the regulation of the production of ferritin, an intracellular iron-binding protein that binds and stores excess cellular iron. The 5' untranslated region of ferritin mRNA contains iron-response elements (IREs) that have a stem-loop structure. The IRE-binding protein (IRE-BP) recognizes five specific bases in the IRE loop and the duplex nature of the stem. At low iron concentrations, IRE-BP is in an active conformation that binds to the IREs (Figure 8-31a). The bound IRE-BP blocks the small ribosomal subunit from scanning for the AUG start codon (see Figure 4-24), thereby inhibiting translation initiation. The resulting decrease in ferritin means less iron is complexed with the ferritin and therefore more is available to iron-requiring enzymes. At high iron concentrations, IRE-BP is in an inactive conformation that does not bind to the 5' IREs, so translation initiation can proceed. The newly synthesized ferritin then binds free iron ions, preventing their accumulation to harmful levels.

The other part of this regulatory system controls the import of iron into cells. In vertebrates, ingested iron is carried through the circulatory system bound to a protein called transferrin. After binding to the transferrin receptor (TfR) in the plasma membrane, the transferrin-iron complex is brought into cells by receptor-mediated endocytosis (Chapter 14). The 3' untranslated region of TfR mRNA contains IREs whose stems have AU-rich destabilizing sequences (Figure 8-31b). At high iron concentrations, when the IRE-BP is in the inactive, nonbinding conformation, these AU-rich sequences promote degradation of TfR mRNA by the same mechanism that leads to rapid degradation of other short-lived mRNAs, as described previously. The resulting decrease in production of the transferrin receptor quickly reduces iron import, thus protecting the cell from excess iron. At low iron concentrations, however, IRE-BP can bind to the 3' IREs in TfR mRNA. The bound IRE-BP blocks recognition of the destabilizing AU-rich sequences by the proteins that would otherwise rapidly degrade the mRNAs. As a result, production of the transferrin receptor increases and more iron is brought into the cell.

Other regulated RNA-binding proteins may also function to control mRNA translation or degradation, much like the dual-acting IRE-BP. For example, a heme-sensitive RNA-binding protein controls translation of the mRNA encoding

FIGURE 8-31 Iron-dependent regulation of mRNA translation and degradation. The iron response element-binding protein (IRE-BP) controls (a) translation of ferritin mRNA and (b) degradation of transferrin-receptor (TfR) mRNA. At low intracellular iron concentrations IRE-BP binds to iron-response elements (IREs) in the 5' or 3' untranslated region of these mRNAs. At high iron concentrations, IRE-BP undergoes a conformational change and cannot bind either mRNA. The dual control by IRE-BP precisely regulates the level of free iron ions within cells. See the text for discussion.

aminolevulinate (ALA) synthase, a key enzyme in the synthesis of heme. Similarly, *in vitro* studies have shown that the mRNA encoding the milk protein casein is stabilized by the hormone prolactin and rapidly degraded in its absence.

Surveillance Mechanisms Prevent Translation of Improperly Processed mRNAs

Translation of an improperly processed mRNA could lead to production of an abnormal protein that interferes with the gene's normal function. This effect is equivalent to that resulting from dominant-negative mutations, discussed in Chapter 5 (Figure 5-44). Several mechanisms collectively termed **mRNA surveillance** help cells avoid the translation of improperly processed mRNA molecules. We have previously mentioned two such surveillance mechanisms: the recognition of improperly processed pre-mRNAs in the nucleus and

their degradation by the exosome, and the general restriction against nuclear export of incompletely spliced pre-mRNAs that remain associated with a spliceosome.

Another mechanism called nonsense-mediated decay (NMD) causes degradation of mRNAs in which one or more exons have been incorrectly spliced. Such incorrect splicing often will alter the open reading frame of the mRNA 3' to the improper exon junction, resulting in introduction of an out-of-frame missense mutation and an incorrect stop codon. For nearly all properly spliced mRNAs, the stop codon is in the last exon. The process of nonsense-mediated decay results in the rapid degradation of mRNAs with stop codons that occur before the last splice junction in the mRNA since in most cases, such mRNAs arise from errors in RNA splicing. However, NMD can also result from a mutation creating a stop codon within a gene or a frame-shifting deletion or insertion. NMD was initially discovered during the study of patients with β^0 -thalassemia, who produce a low level of β -globin protein associated with a low level of β -globin mRNA (Figure 8-32a, b).

A search for possible molecular signals that might indicate the positions of splice junctions in a processed mRNA led to the discovery of exon-junction complexes. As noted already, these complexes of several proteins (including Y14, Magoh, eIF4III, UPF2, UPF3, and REF), bind ~20 nucleotides 5' to an exon-exon junction following RNA splicing (Figure 8-32c), stimulate export of mRNPs from the nucleus by interacting with the mRNA exporter (see Figure 8-21). Analysis of yeast mutants indicated that one of the proteins in exon-junction complexes (UPF3) functions in nonsense-mediated decay. In the cytoplasm, this component of exon-junction complexes interacts with a protein (UPF1) and a protein kinase (SMG1) that phosphorylates UPF1, causing the mRNA to associate with P bodies, repressing translation of the mRNA. An additional protein (UPF2) associated with the mRNP complex binds a P-body associated deadenylase that rapidly removes the poly(A) tail from an associated mRNA, leading to its rapid decapping and degradation by the P-body associated 5'→3' exonuclease (see Figure 8-29). In the case of properly spliced mRNAs, the exon-junction complexes associate with the nuclear cap-binding complex (CBP80, CBP20) as the mRNP is transported through a nuclear pore complex, thereby protecting the mRNA from degradation. The exon-junction complexes are thought to be dislodged from the mRNA by passage of the first "pioneer" ribosome to translate the mRNA. However, for mRNAs with a stop codon before the final exon junction, one or more exon-junction complexes remain associated with the mRNA, resulting in nonsense-mediated decay (Figure 8-32).

Localization of mRNAs Permits Production of Proteins at Specific Regions Within the Cytoplasm

Many cellular processes depend on localization of particular proteins to specific structures or regions of the cell. In later chapters we examine how some proteins are transported *after* their synthesis to their proper cellular location. Alternatively,

FIGURE 8-32 Discovery of nonsense-mediated mRNA decay (NMD). (a) Patients with β^0 -thalassemia express very low levels of β -globin mRNA. A common cause of this syndrome is a single-base-pair deletion in exon 1 or exon 2 of the β -globin gene. Ribosomes translating the mutant mRNA read out of frame following the deletion and encounter a stop codon in the wrong reading frame before they translate across the last exon junction in the mRNA. Consequently, they do not displace an exon-junction complex (EJC) from the mRNA. Cytoplasmic proteins associate with the EJC and induce degradation of the mRNA. (b) Bone marrow was obtained from a patient with a wild-type β -globin gene and from a patient with β^0 -thalassemia. RNA was isolated from the bone marrow cells shortly after collection, or 30 min after incubation in media with Actinomycin D, a drug that inhibits transcription. The amount of β -globin RNA was measured using the S1-nuclease protection method (arrow). The patient with

β^0 -thalassemia had much less β -globin mRNA than the patient with a wild-type β -globin gene (– Act D). The mutant β -globin mRNA decayed rapidly when transcription was inhibited (+ Act D), whereas the wild-type β -globin mRNA remained stable. (c) Current model of NMD. PTC, premature termination codon. Norm Term, the normal termination codon. SURF, complex of protein kinase SMG1, UPF1, and translation termination factors eRF1 and eRF3. Formation of the SURF complex leads to phosphorylation of UPF1 and association of phospho-UPF1 with a UPF2-UPF3 complex bound to any exon-exon junction complexes that were not displaced from the mRNA by the first, pioneer ribosome to translate the message. This leads to the association of the PTC-containing mRNA with P-bodies, removal of the poly(A) tail, and degradation of the mRNA. [Part (b) from L. E. Maquat et al., 1981, *Cell* 27:543. Part (c) adapted from J. Hwang et al., 2010, *Mol. Cell* 39:396.]

protein localization can be achieved by localization of mRNAs to specific regions of the cytoplasm in which their encoded proteins function. In most cases examined thus far, such mRNA localization is specified by sequences in the 3' untranslated region of the mRNA. A recent genomic-level study of mRNA localization in *Drosophila* embryos revealed that ~70 percent

of 3000 mRNAs analyzed were localized to specific subcellular regions, raising the possibility that this is a much more general phenomenon than previously appreciated.

Localization of mRNAs to the bud in *S. cerevisiae* The most thoroughly understood example of mRNA localization occurs

FIGURE 8-33 Switching of mating type in haploid yeast cells.

(a) Division by budding forms a larger mother cell (M) and smaller daughter cell (D), both of which have the same mating type as the original cell (α in this example). The mother cell can switch mating type during G₁ of the next cell cycle and then divide again, producing two cells of the opposite type (a in this example). Switching depends on transcription of the *HO* gene, which occurs only in the absence of Ash1 protein. The smaller daughter cells, which produce Ash1 protein, cannot switch; after growing in size through interphase, they divide to form a mother cell and daughter cell. (b) Model for restriction of mating-type switching to mother cells in *S. cerevisiae*. Ash1 protein prevents a cell from transcribing the *HO* gene whose encoded protein initiates the DNA rearrangement that results in mating-type switching from a to α or α to a . Switching occurs only in the mother cell, after it separates from a newly budded daughter cell, because the Ash1 protein is present only in the daughter cell. The molecular basis for this differential localization of Ash1 is the one-way transport of *ASH1* mRNA into the bud. A linking protein, She2, binds to specific 3' untranslated sequences in the *ASH1* mRNA and also binds to She3 protein. This protein in turn binds to a myosin motor, Myo4, which moves along actin filaments into the bud. [See S. Koon and B. J. Schnapp, 2001, *Curr. Biology* 11:R166.]

in the budding yeast *S. cerevisiae*. As discussed in Chapter 7, whether a haploid yeast cell exhibits the a or α mating type is determined by whether a a or α genes are present at the expressed *MAT* locus on chromosome III (see Figure 7-33). The process that transfers a a or α genes from the silent mating-type locus to the expressed *MAT* locus is initiated by a sequence-specific endonuclease called *HO*. Transcription of the *HO* gene is dependent on the SWI/SNF chromatin-remodeling complex (see Chapter 7, Section 7.5). Daughter yeast cells arising by budding from mother cells contain a transcriptional repressor called Ash1 (for Asymmetric synthesis of *HO*) that prevents recruitment of the SWI/SNF complex to the *HO* gene, thereby preventing its transcription. The absence of Ash1 from mother cells allows them to transcribe the *HO* gene. As a consequence mother cells switch their mating type, while daughter cells generated by budding do not (Figure 8-33a).

Ash1 protein accumulates only in daughter cells because the mRNA encoding it is localized to daughter cells. The localization process requires three proteins: She2 (for SWI-dependent *HO* expression), an RNA-binding protein that binds specifically to a localization signal with a specific RNA structure in the *ASH1* mRNA; Myo4, a myosin motor protein that moves cargos on actin filaments (see Chapter 17); and She3, which links She2 and therefore *ASH1* mRNA to Myo4 (Figure 8-33b). *ASH1* mRNA is transcribed in the nucleus of the mother cell before mitosis. Movement of Myo4 with its bound *ASH1* mRNA along actin filaments that extend from the mother cell into the bud carries the *ASH1* mRNA into the growing bud before cell division.

At least 23 other mRNAs were found to be transported by the She2, She3, Myo4 system. All have an RNA localiza-

tion signal to which She2 binds, usually in their 3' UTR. The process can be visualized in live cells by the experiment shown in Figure 8-34. RNAs can be fluorescently labeled by including in their sequence high-affinity binding sites for RNA-binding proteins, such as bacteriophage proteins MS2 coat protein and bacteriophage λ N protein, that bind to different stem loops of specific sequence (Figure 8-34a). When such engineered mRNAs are expressed in budding yeast cells along with the bacteriophage proteins fused to proteins that fluoresce different colors, the fusion proteins bind to these specific RNA sequences, thereby labeling the RNAs that contain them with different colors. In the experiment shown in Figure 8-34b, *ASH1* mRNA was labeled by the binding of green fluorescent protein fused to λ N. Another mRNA localized to the bud by this system, the *IST2* mRNA encoding a component of the growing bud membrane, was labeled by the binding of red fluorescent protein fused to MS2 coat protein. Video of a budding cell showed that the differently labeled *ASH1* and *IST2* mRNAs accumulated in the same large cytoplasmic RNP particle containing multiple mRNAs in the mother cell cytoplasm, as can be seen from the merge

EXPERIMENTAL FIGURE 8-34 Transport of mRNP particles from a yeast mother cell into the bud. (a) Yeast cells were engineered to express an ASH1 mRNA with binding sites for the bacteriophage λ N protein in its 5' untranslated region and an IST2 mRNA with binding sites for bacteriophage MS2 coat protein in its 3' untranslated region. A fusion of green fluorescent protein to λ N protein (GFP- λ N) and a fusion of red fluorescent protein to MS2 coat protein (RFP-MS2) also were expressed in the same cells. In other experiments, these fluorescently tagged sequence-specific RNA-binding proteins were shown to bind to their own specific binding sites engineered into the ASH1 and IST2 mRNAs, and not to each others' binding sites. Both fluorescently tagged proteins also contained a nuclear localization signal so that the fluorescent proteins that were not bound to their high-affinity binding sites in these mRNAs were transported into nuclei through nuclear pore complexes (see Chapter 13). This was necessary to prevent high fluorescence from excess GFP- λ N and RFP-MS2 in the cytoplasm. At

the right, GFP- λ N and RFP-MS2 were independently visualized by using millisecond alternating laser excitation of GFP and RFP. (b) Frames from a video of fluorescing cells are shown. The nucleus next to the large vacuole in the mother cell near the center of the micrographs, as well as nuclei in neighboring cells, was observed by green and red fluorescence as shown in the top and middle rows. A merge of the two images is shown in the bottom row, which also indicates the time elapsed between images. An RNP particle containing both the ASH1 mRNA with λ N-binding sites and the IST2 mRNA with MS2-binding sites was observed in the mother cell cytoplasm in the left column of images (arrow). The particle increased in intensity between 0.00 and 46.80 seconds, indicating that more of these mRNAs joined the RNP particle. The RNP particle was transported into the bud between 46.80 and 85.17 seconds and then became localized to the bud tip.

[From S. Lange et al., 2008, *Traffic* 9:1256. See this paper to view the video.]

of the green and red fluorescent signals. The RNP particle was then transported into the bud within about one minute.

Localization of mRNAs to synapses in the mammalian nervous system As mentioned earlier, in neurons, localization of specific mRNAs at synapses far from the nucleus in the cell body plays an essential function in learning and memory (Figure 8-35). Like the localized mRNAs in yeast, these mRNAs contain RNA localization signals in their 3' untranslated region. Some of these mRNAs are initially synthesized with

short poly(A) tails that do not allow translation initiation. Once again, large RNP particles containing multiple mRNAs bearing localization signals form in the cytoplasm near the cell nucleus. In this case, the RNP particles are transported down the axon to synapses by kinesin motor proteins that travel down microtubules extending the length of the axon (see Chapter 18). Electrical activity at a given synapse may

EXPERIMENTAL FIGURE 8-35 A specific neuronal mRNA

localizes to synapses. Sensory neurons from the sea slug *Aplysia californica* were cultured with target motor neurons so that processes from the sensory neurons formed synapses with processes from the motor neurons. The micrograph at the left shows motor neuron processes visualized with a blue fluorescent dye. GFP-VAMP (green) was expressed in sensory neurons and marks the location of synapses formed between sensory and motor neuron processes (arrows). The micrograph on the right shows red fluorescence from in situ hybridization of an antisensorin mRNA probe. Sensorin is a neurotransmitter expressed by the sensory neuron only; sensory neuron processes are not otherwise visualized in this preparation, but they lie adjacent to the motor neuron processes. The in situ hybridization results indicate that sensorin mRNA is localized to synapses. [From V. Lyles, Y. Zhao, and K. C. Martin, 2006, *Neuron* 49:323.]

then stimulate the mRNAs' polyadenylation in the region of the synapse, activating the translation of encoded proteins that increase the size and alter the neurophysiological properties of the one synapse while leaving unaffected the hundreds to thousands of other synapses made by the neuron.

KEY CONCEPTS of Section 8.4

Cytoplasmic Mechanisms of Post-transcriptional Control

- Translation can be repressed by micro RNAs (miRNAs), which form imperfect hybrids with sequences in the 3' untranslated region (UTR) of specific target mRNAs.
- The related phenomenon of RNA interference, which probably evolved as an early defense system against viruses and transposons, leads to degradation of mRNAs that form perfect hybrids with short interfering RNAs (siRNAs).
- Both miRNAs and siRNAs contain 21–23 nucleotides, are generated from longer precursor molecules, and are bound by an Argonaute protein and assembled into a multiprotein RNA-induced silencing complex (RISC) that either represses translation of target mRNAs or cleaves them (see Figures 8-25 and 8-26).
- Cytoplasmic polyadenylation is required for translation of mRNAs with a short poly(A) tail. Binding of a specific protein to regulatory elements in their 3' UTRs represses translation of these mRNAs. Phosphorylation of this RNA-binding protein, induced by an external signal, leads to lengthening of the 3' poly(A) tail and thus translation (see Figure 8-28).
- Most mRNAs are degraded as the result of the gradual shortening of their poly(A) tail (deadenylation) followed by exosome-mediated 3'→5' digestion, or removal of the 5' cap and digestion by a 5'→3' exonuclease (see Figure 8-29).
- Eukaryotic mRNAs encoding proteins that are expressed in short bursts generally have repeated copies of an AU-rich sequence in their 3' UTR. Specific proteins that bind to these elements also interact with the deadenylating enzyme and cytoplasmic exosomes, promoting rapid RNA degradation.
- Binding of various proteins to regulatory elements in the 3' or 5' UTRs of mRNAs regulates the translation or degradation of many mRNAs in the cytoplasm.
- Translation of ferritin mRNA and degradation of transferrin receptor (TfR) mRNA are both regulated by the same iron-sensitive RNA-binding protein. At low iron concentrations, this protein is in a conformation that binds to specific elements in the mRNAs, inhibiting ferritin mRNA translation or degradation of TfR mRNA (see Figure 8-31). This dual control precisely regulates the iron level within cells.
- Nonsense-mediated decay and other mRNA surveillance mechanisms prevent the translation of improperly processed mRNAs encoding abnormal proteins that might interfere with functioning of the corresponding normal proteins.

- Many mRNAs are transported to specific subcellular locations by sequence-specific RNA-binding proteins that bind localization sequences usually found in the 3' UTR. These RNA-binding proteins then associate directly or via intermediary proteins with motor proteins that carry large RNP complexes with many mRNAs bearing the same localization signal on actin or microtubule fibers to specific locations in the cytoplasm.

8.5 Processing of rRNA and tRNA

Approximately 80 percent of the total RNA in rapidly growing mammalian cells (e.g., cultured-HeLa cells) is rRNA, and 15 percent is tRNA; protein-coding mRNA thus constitutes only a small portion of the total RNA. The primary transcripts produced from most rRNA genes and from tRNA genes, like pre-mRNAs, are extensively processed to yield the mature, functional forms of these RNAs.

The ribosome is a highly evolved, complex structure (see Figure 4-23), optimized for its function in protein synthesis. Ribosome synthesis requires the function and coordination of all three nuclear RNA polymerases. The 28S and 5.8S rRNAs associated with the large ribosomal subunit and the single 18S rRNA of the small subunit are transcribed by RNA polymerase I. The 5S rRNA of the large subunit is transcribed by RNA polymerase III, and the mRNAs encoding the ribosomal proteins are transcribed by RNA polymerase II. In addition to the four rRNAs and ~70 ribosomal proteins, at least 150 other RNAs and proteins interact transiently with the two ribosomal subunits during their assembly through a series of coordinated steps. Furthermore, multiple specific bases and riboses of the mature rRNAs are modified to optimize their function in protein synthesis. Although most of the steps in ribosomal subunit synthesis and assembly occur in the nucleolus (a subcompartment of the nucleus not bounded by a membrane), some occur in the nucleoplasm during passage from the nucleolus to nuclear pore complexes. A quality-control step occurs before nuclear export so that only fully functional subunits are exported to the cytoplasm, where the final steps of ribosome subunit maturation occur. tRNAs also are processed from precursor primary transcripts in the nucleus and modified extensively before they are exported to the cytoplasm and used in protein synthesis. First we'll discuss the processing and modification of rRNA and the assembly and nuclear export of ribosomes. Then we'll consider the processing and modification of tRNAs.

Pre-rRNA Genes Function as Nucleolar Organizers and Are Similar in All Eukaryotes

The 28S and 5.8S rRNAs associated with the large (60S) ribosomal subunit and the 18S rRNA associated with the small (40S) ribosomal subunit in higher eukaryotes (and the

EXPERIMENTAL FIGURE 8-36 Electron micrograph of pre-rRNA transcription units from the nucleolus of a frog oocyte. Each "feather" represents multiple pre-rRNA molecules associated with protein in a pre-ribonucleoprotein complex (pre-rRNP) emerging from a transcription unit. Note the dense "knob" at the 5' end of each nascent pre-RNP thought to be a processome. Pre-rRNA transcription units are arranged in tandem, separated by nontranscribed spacer regions of nucleolar chromatin. [Courtesy of Y. Osheim and O. J. Miller, Jr.]

functionally equivalent rRNAs in all other eukaryotes) are encoded by a single type of pre-rRNA transcription unit. In human cells, transcription by RNA polymerase I yields a 45S (~13.7 kb) primary transcript (pre-rRNA), which is processed into the mature 28S, 18S, and 5.8S rRNAs found in cytoplasmic ribosomes. The fourth rRNA, 5S, is encoded separately and transcribed outside the nucleolus. Sequencing of the DNA encoding the 45S pre-rRNA from many species showed that this DNA shares several properties in all eukaryotes. First, the pre-rRNA genes are arranged in long tandem arrays separated by nontranscribed spacer regions ranging in length from ~2 kb in frogs to ~30 kb in humans (Figure 8-36). Second, the genomic regions corresponding to the three mature rRNAs are always arranged in the same 5'→3' order: 18S, 5.8S, and 28S. Third, in all eukaryotic cells (and even in bacteria), the pre-rRNA gene codes for regions that are removed during processing and rapidly degraded. These regions probably contribute to proper folding of the rRNAs but are not required once the folding has occurred. The general structure of pre-rRNAs is diagrammed in Figure 8-37.

The synthesis and most of the processing of pre-rRNA occurs in the nucleolus. When pre-rRNA genes initially were identified in the nucleolus by in situ hybridization, it was not known whether any other DNA was required to form the nucleolus. Subsequent experiments with transgenic *Drosophila* strains demonstrated that a single complete pre-rRNA transcription unit induces formation of a small nucleolus. Thus a single pre-rRNA gene is sufficient to be a *nucleolar organizer*, and all the other components of the ribosome diffuse to the newly formed pre-rRNA. The structure of the nucleolus observed by light and electron microscopy results from the processing of pre-rRNA and the assembly of ribosomal subunits.

Small Nucleolar RNAs Assist in Processing Pre-rRNAs

Ribosomal subunit assembly, maturation, and export to the cytoplasm are best understood in the yeast *S. cerevisiae*. However, nearly all the proteins and RNAs involved are highly conserved in multicellular eukaryotes, where the fundamental aspects of ribosome biosynthesis are likely to be the same. As for pre-mRNAs, nascent pre-rRNA transcripts are immediately bound by proteins, forming preribosomal ribonucleoprotein particles (pre-rRNPs). For reasons not yet known, cleavage of the pre-rRNA does not begin until transcription of the pre-rRNA is nearly complete. In yeast, it takes approximately six minutes for a pre-rRNA to be transcribed. Once transcription is complete, the rRNA is cleaved, and bases and riboses are modified in about 10 seconds. In a rapidly growing yeast cell, ~40 pairs of ribosomal subunits are synthesized, processed, and transported to the cytoplasm every second. This extremely high rate of ribosome synthesis despite the seemingly long period required to transcribe a pre-rRNA is possible because pre-rRNA genes are packed

FIGURE 8-37 General structure of eukaryotic pre-rRNA transcription units. The three coding regions (red) encode the 18S, 5.8S, and 28S rRNAs found in ribosomes of higher eukaryotes or their equivalents in other species. The order of these coding regions in the genome is always 5'→3'. Variations in the lengths of the transcribed spacer regions (blue) account for the major difference in the lengths of pre-rRNA transcription units in different organisms.

with RNA polymerase I molecules transcribing the same gene simultaneously (see Figure 8-36) and because there are 100–200 such genes on chromosome XII, the yeast nucleolar organizer.

The primary transcript of ~7 kb is cut in a series of cleavage and exonucleolytic steps that ultimately yield the mature rRNAs found in ribosomes (Figure 8-38). During processing, pre-rRNA also is extensively modified, mostly by methylation of the 2'-hydroxyl group of specific riboses and conversion of specific uridine residues to pseudouridine. These post-transcriptional modifications of rRNA are probably important for protein synthesis, because they are highly conserved. Virtually all of these modifications occur in the most conserved core structure of the ribosome, which is directly

involved in protein synthesis. The positions of the specific sites of 2'-O-methylation and pseudouridine formation are determined by approximately 150 different small nucleolus-restricted RNA species, called **small nucleolar RNAs (snoRNAs)**, which hybridize transiently to pre-rRNA molecules. Like the snRNAs that function in pre-mRNA processing, snoRNAs associate with proteins, forming ribonucleoprotein particles called snoRNPs. One class of more than 40 snoRNPs (containing box C+D snoRNAs) positions a methyltransferase enzyme near methylation sites in the pre-mRNA. The multiple different box C+D snoRNAs direct methylation at multiple sites through a similar mechanism. They share common sequence and structural features and are bound by a common set of proteins. One or two regions

FIGURE 8-38 rRNA processing. Endoribonucleases that make internal cleavages are represented as scissors. Exoribonucleases that digest from one end, either 5' or 3', are shown as Pac-Men. Most 2'-O-ribose methylation (CH₃) and generation of pseudouridines in the

rRNAs occurs following the initial cleavage at the 3' end, before the initial cleavage at the 5' end. Proteins and snoRNPs known to participate in these steps are indicated. [From J. Venema and D. Tollervey, 1999, *Ann. Rev. Genetics* 33:261.]

FIGURE 8-39 snoRNP-directed modification of pre-rRNA. (a) A snoRNA called box C+D snoRNA is involved in ribose 2'-O-methylation. Sequences in this snoRNA hybridize to two different regions in the pre-rRNA, directing methylation at the indicated sites. (b) Box H+ACA snoRNAs fold into two stem loops with internal single-stranded bulges

in the stems. Pre-rRNA hybridizes to the single-stranded bulges, demarcating a site of pseudouridylation. (c) Conversion from uridine to pseudouridine directed by the box H+ACA snoRNAs of part (b). [Part (a) from T. Kiss, 2001, *EMBO J.* **20**:3617. Part (b) from U. T. Meier, 2005, *Chromosoma* **114**:1.]

of each of these snoRNAs are precisely complementary to sites on the pre-rRNA and direct the methyltransferase to specific riboses in the hybrid region (Figure 8-39a). A second major class of snoRNPs (containing box H+ACA snoRNAs) positions the enzyme that converts uridine to pseudouridine (Figure 8-39b). This conversion involves rotation of the pyrimidine ring (Figure 8-39c). Bases on either side of the modified uridine in the pre-rRNA base-pair with bases in the bulge of a stem in the H+ACA snoRNAs, leaving the modified uridine bulged out of the helical double-stranded region, like the branch point A bulges out in pre-mRNA spliceosomal splicing (see Figure 8-10). Other modifications of pre-rRNA nucleotides, such as adenine dimethylation, are carried out by specific proteins without the assistance of guiding snoRNAs.

The U3 snoRNA is assembled into a large snoRNP containing ~72 proteins called the small subunit (SSU) processome, which specifies cleavage at site A₀, the initial cut near the 5' end of the pre-rRNA (see Figure 8-38). U3 snoRNA base-pairs with an upstream region of the pre-rRNA to specify the location of the cleavage. The processome is thought to form the "5' knob" visible in electron micrographs of pre-rRNPs (see Figure 8-36). Base pairing of other snoRNPs specify additional cleavage reactions that remove transcribed spacer regions. The first cleavage to initiate processing of the 5.8S and 25S rRNAs of the large subunit is performed by RNase MRP, a complex of nine proteins with an RNA. Once cleaved from pre-rRNAs, these sequences are degraded by the same exosome-associated 3'→5' nuclear exonucleases that degrade introns spliced from pre-mRNAs. Nuclear 5'→3' exonucleases (Rat1; Xrn1) also remove some regions of 5' spacer.

Some snoRNAs are expressed from their own promoters by RNA polymerase II or III. Remarkably, however, the large majority of snoRNAs are processed from spliced-out introns of genes encoding functional mRNAs for proteins involved in ribosome synthesis or translation. Some snoRNAs are processed from introns spliced from apparently nonfunctional mRNAs. The genes encoding these mRNAs seem to exist only to express snoRNAs from excised introns.

Unlike 18S, 5.8S, and 28S genes, 5S rRNA genes are transcribed by RNA polymerase III in the nucleoplasm outside the nucleolus. With only minor additional processing to remove nucleotides at the 3' end, 5S rRNA diffuses to the nucleolus, where it assembles with the pre-rRNA precursor and remains associated with the region that is cleaved into the precursor of the large ribosomal subunit.

Most of the ribosomal proteins of the small 40S ribosomal subunit associate with the nascent pre-rRNA during transcription (Figure 8-40). Cleavage of the full-length pre-rRNA in the 90S RNP precursor releases a pre-40S particle that requires only a few more remodeling steps before it is transported to the cytoplasm. Once the pre-40S particle leaves the nucleolus, it traverses the nucleoplasm quickly and is exported through nuclear pore complexes (NPCs), as discussed below. Final maturation of the small ribosomal subunit occurs in the cytoplasm: exonucleolytic processing of the 20S rRNA into mature small subunit 18S rRNA by the cytoplasmic 5'→3' exoribonuclease Xrn1 and the dimethylation of two adjacent adenines near the 3' end of 18S rRNA by the cytoplasmic enzyme Dim1.

In contrast to the pre-40S particle, the precursor of the large subunit requires considerably more remodeling through

FIGURE 8-40 Ribosomal subunit assembly. Ribosomal proteins and RNAs in the maturing small and large ribosomal subunits are depicted in blue, with a shape similar to the icons for the mature

subunits in the cytoplasm. Other factors that associate transiently with the maturing subunits are depicted in different colors, as shown in the key. [From H. Tschöchner and E. Hurt, 2003, *Trends Cell Biol.* 13:255.]

many more transient interactions with nonribosomal proteins before it is sufficiently mature for export to the cytoplasm. Consequently, it takes a considerably longer period for the maturing 60S subunit to exit the nucleus (30 minutes compared to 5 minutes for export of the 40S subunit in cultured human cells). Multiple presumptive RNA helicases and small G proteins are associated with the maturing pre-60S subunits. Some RNA helicases are necessary to dislodge the snoRNPs that base-pair perfectly with pre-rRNA over up to 30 base pairs. Other RNA helicases may function in the disruption of protein-RNA interactions. The requirement for so many GTPases suggests that there are many quality-control checkpoints in the assembly and remodeling of the large subunit RNP, where one step must be completed before a GTPase is activated to allow the next step to proceed. Members of the AAA ATPase family are also bound transiently. This class of proteins is often involved in large molecular movements and may be required to fold the complex, large rRNA into the proper conformation. Some steps in 60S subunit maturation

occur in the nucleoplasm, during passage from the nucleolus to nuclear pore complexes (see Figure 8-40). Much remains to be learned about the complex, fascinating, and essential remodeling processes that occur during formation of the ribosomal subunits.

The large ribosomal subunit is one of the largest structures to pass through nuclear pore complexes. Maturation of the large subunit in the nucleoplasm leads to the generation of binding sites for a nuclear export adapter called Nmd3. Nmd3 is bound by the nuclear transporter Exportin1 (also called Crm1). This is another quality-control step, because only correctly assembled subunits can bind Nmd3 and be exported. The small subunit of the mRNA exporter (NXT1) also becomes associated with the nearly mature large ribosomal subunit. These nuclear transporters interact with FG-domains of FG-nucleoporins. This mechanism allows penetration of the molecular "cloud" that fills most of the central channel of the NPC (see Figure 8-20). Several specific nucleoporins without FG-domains are also required for ribosomal subunit

export and may have additional functions specific for this task. The dimensions of ribosomal subunits (~25–30 nm in diameter) and the central channel of the NPC are comparable, so passage may not require distortion of either the ribosomal subunit or the channel. Final maturation of the large subunit in the cytoplasm includes removal of these export factors. As for the export of most macromolecules from the nucleus, including tRNAs and pre-miRNAs (but not most mRNPs), ribosome subunit export requires the function of a small G protein called Ran, as discussed in Chapter 13.

Self-Splicing Group I Introns Were the First Examples of Catalytic RNA

During the 1970s, the pre-rRNA genes of the protozoan *Tetrahymena thermophila* were discovered to contain an intron. Careful searches failed to uncover even one pre-rRNA gene without the extra sequence, indicating that splicing is required to produce mature rRNA in these organisms. In 1982, *in vitro* studies showing that the pre-rRNA was spliced at the correct sites in the absence of any protein provided the first indication that RNA can function as a catalyst, like enzymes.

A whole raft of self-splicing sequences subsequently were found in pre-rRNAs from other single-celled organisms, in mitochondrial and chloroplast pre-rRNAs, in several pre-mRNAs from certain *E. coli* bacteriophages, and in some bacterial tRNA primary transcripts. The self-splicing sequences in all these precursors, referred to as *group I introns*, use guanosine as a cofactor and can fold by internal base pairing to juxtapose closely the two exons that must be joined. As discussed earlier, certain mitochondrial and chloroplast pre-mRNAs and tRNAs contain a second type of self-splicing intron, designated group II.

The splicing mechanisms used by group I introns, group II introns, and spliceosomes are generally similar, involving two transesterification reactions, which require no input of energy (Figure 8-41). Structural studies of the group I intron from *Tetrahymena* pre-rRNA combined with mutational and biochemical experiments have revealed that the RNA folds into a precise three-dimensional structure that, like protein enzymes, contains deep grooves for binding substrates and solvent-inaccessible regions that function in catalysis. The group I intron functions like a metalloenzyme to precisely orient the atoms that participate in the two transesterification

FIGURE 8-41 Splicing mechanisms in group I and group II self-splicing introns and spliceosome-catalyzed splicing of pre-mRNA. The intron is shown in gray, the exons to be joined in red. In group I introns, a guanosine cofactor (G) that is not part of the RNA chain associates with the active site. The 3'-hydroxyl group of this guanosine participates in a transesterification reaction with the phosphate at the 5' end of the intron; this reaction is analogous to that

involving the 2'-hydroxyl groups of branch-site As in group II introns and pre-mRNA introns spliced in spliceosomes (see Figure 8-8). The subsequent transesterification that links the 5' and 3' exons is similar in all three splicing mechanisms. Note that spliced-out group I introns are linear structures, unlike the branched intron products in the other two cases. [Adapted from P. A. Sharp, 1987, *Science* **235**:769.]

reactions adjacent to catalytic Mg^{2+} ions. Considerable evidence now indicates that splicing by group II introns and by snRNAs in the spliceosome also involves bound catalytic Mg^{2+} ions. In both the group I and II self-splicing introns and probably in the spliceosome, RNA functions as a **ribozyme**, an RNA sequence with catalytic ability.

Pre-tRNAs Undergo Extensive Modification in the Nucleus

Mature cytosolic tRNAs, which average 75–80 nucleotides in length, are produced from larger precursors (pre-tRNAs) synthesized by RNA polymerase III in the nucleoplasm. Mature tRNAs also contain numerous modified bases that are not present in tRNA primary transcripts. Cleavage and base modification occur during processing of all pre-tRNAs; some pre-tRNAs also are spliced during processing. All of these processing and modification events occur in the nucleus.

A 5' sequence of variable length that is absent from mature tRNAs is present in all pre-tRNAs (Figure 8-42). This occurs because the 5' end of mature tRNAs is generated by an endonucleolytic cleavage specified by the tRNA three-dimensional structure rather than the start site of transcription. These extra 5' nucleotides are removed by ribonuclease P (RNase P), a ribonucleoprotein endonuclease. Studies with *E. coli* RNase P indicate that at high Mg^{2+} concentrations, the RNA component alone can recognize and cleave *E. coli* pre-tRNAs. The

RNase P polypeptide increases the rate of cleavage by the RNA, allowing it to proceed at physiological Mg^{2+} concentrations. A comparable RNase P functions in eukaryotes.

About 10 percent of the bases in pre-tRNAs are modified enzymatically during processing. Three classes of base modifications occur (Figure 8-42): (1) U residues at the 3' end of pre-tRNA are replaced with a CCA sequence. The CCA sequence is found at the 3' end of all tRNAs and is required for their charging by aminoacyl-tRNA synthetases during protein synthesis. This step in tRNA synthesis likely functions as a quality-control point, since only properly folded tRNAs are recognized by the CCA addition enzyme. (2) Methyl and isopentenyl groups are added to the heterocyclic ring of purine bases, and the 2'-OH groups in the ribose of specific residues are methylated. (3) Specific uridines are converted to dihydrouridine, pseudouridine, or ribothymidine residues. The functions of these base and ribose modifications are not well understood, but since they are highly conserved, they probably have a positive influence on protein synthesis.

As shown in Figure 8-42, the pre-tRNA expressed from the yeast tyrosine tRNA ($tRNA^{Tyr}$) gene contains a 14-base intron that is not present in mature $tRNA^{Tyr}$. Some other eukaryotic tRNA genes and some archaeal tRNA genes also contain introns. The introns in nuclear pre-tRNAs are shorter than those in pre-mRNAs and lack the consensus splice-site sequences found in pre-mRNAs (see Figure 8-7). Pre-tRNA introns also are clearly distinct from the much longer self-splicing group I

FIGURE 8-42 Changes that occur during the processing of tyrosine pre-tRNA. A 14-nucleotide intron (blue) in the anticodon loop is removed by splicing. A 16-nucleotide sequence (green) at the 5' end is cleaved by RNase P. U residues at the 3' end are replaced by the CCA sequence (red) found in all mature tRNAs. Numerous bases in

the stem loops are converted to characteristic modified bases (yellow). Not all pre-tRNAs contain introns that are spliced out during processing, but they all undergo the other types of changes shown here. D = dihydrouridine; ψ = pseudouridine.

and group II introns found in chloroplast and mitochondrial pre-rRNAs. The mechanism of pre-tRNA splicing differs in three fundamental ways from the mechanisms utilized by self-splicing introns and spliceosomes (see Figure 8-41). First, splicing of pre-tRNAs is catalyzed by proteins, not by RNAs. Second, a pre-tRNA intron is excised in one step that entails simultaneous cleavage at both ends of the intron. Finally, hydrolysis of GTP and ATP is required to join the two tRNA halves generated by cleavage on either side of the intron.

After pre-tRNAs are processed in the nucleoplasm, the mature tRNAs are transported to the cytoplasm through nuclear pore complexes by Exportin-t, as discussed previously. In the cytoplasm, tRNAs are passed between aminoacyl-tRNA synthetases, elongation factors, and ribosomes during protein synthesis (Chapter 4). Thus tRNAs generally are associated with proteins and spend little time free in the cell, as is also the case for mRNAs and rRNAs.

Nuclear Bodies Are Functionally Specialized Nuclear Domains

High-resolution visualization of plant- and animal-cell nuclei by electron microscopy and subsequent staining with fluorescently labeled antibodies has revealed domains in nuclei in addition to chromosome territories and nucleoli. These specialized nuclear domains, called **nuclear bodies**, are not surrounded by membranes but are nonetheless regions of high concentrations of specific proteins and RNAs that form distinct, roughly spherical structures within the nucleus. The most prominent nuclear bodies are nucleoli, the sites of ribosomal subunit synthesis and assembly discussed earlier. Several other types of nuclear bodies also have been described in structural studies.

Experiments with fluorescently labeled nuclear proteins have shown that the nucleus is a highly dynamic environment, with rapid diffusion of proteins through the nucleoplasm. Proteins associated with nuclear bodies are often also observed at lower concentrations in the nucleoplasm outside the nuclear bodies, and fluorescence studies indicate that they diffuse in and out of the nuclear bodies. Based on these measurements of molecular mobility in living cells, nuclear bodies can be mathematically modeled as the expected steady state for diffusing proteins that interact with sufficient affinity to form self-organized regions of high concentrations of specific proteins but with low enough affinity for each other to be able to diffuse in and out of the structure. In electron micrographs these structures appear to be a heterogeneous, spongelike network of interacting components. We discuss a few examples of nuclear bodies here.

Cajal Bodies Cajal bodies are ~0.2–1 μm spherical structures that have been observed in large nuclei for more than a century (Figure 8-43). Current research indicates that like nucleoli, Cajal bodies are centers of RNP-complex assembly for spliceosomal snRNPs and other RNPs. Like rRNAs, snRNAs undergo specific modifications, such as the conversion of specific uridine residues to pseudouridine and addition of

FIGURE 8-43 Nuclear bodies are differentially permeable to molecules in the bulk nucleoplasm. Each pair of panels shows a single area through a living *Xenopus* oocyte nucleus that was previously injected with fluorescent dextran of the indicated molecular mass (3–2000 kDa). Each section of the upper panel is a confocal image in which the intensity of fluorescence is a measure of dextran concentration (i.e., darker areas show regions where dextran has been excluded). Each section of the lower panel is a differential interference contrast image of the same field. Open arrowheads indicate nucleoli, closed arrowheads Cajal bodies (CBs) with attached nuclear speckles which are much larger in *Xenopus* oocytes than in most somatic cells. Dextrans of low molecular mass (e.g., 3 kDa) almost completely penetrated CBs but were excluded more from nuclear speckles and nucleoli. Exclusion of dextran increased with molecular mass. Bar = 10 μm . [From K. E. Handwerger et al., 2005, *Mol. Biol. Cell* 16:202.]

methyl groups to the 2'-hydroxyl groups of specific riboses. These post-transcriptional modifications are important for the proper assembly and function of snRNPs in pre-mRNA splicing. These modifications occur in Cajal bodies, where they are directed by a class of snoRNA-like guide RNA molecules called *scaRNAs* (small Cajal body-associated RNAs). There is also evidence that the Cajal body is the site of reassembly of the U4/U6/U5 tri-snRNP complexes required for pre-mRNA splicing from the free U4, U5, and U6 snRNPs released during the removal of each intron (see Figure 8-11). Since Cajal bodies also contain a high concentration of the U7 snRNP involved in the specialized 3'-end processing of the major histone mRNAs, it is likely that this process also occurs in Cajal bodies, as may the assembly of the telomerase RNP.

Nuclear Speckles Nuclear speckles were observed, using fluorescently labeled antibodies to snRNP proteins and other proteins involved in pre-mRNA splicing, as approximately 25–50 irregular, amorphous structures 0.5–2 μm in diameter that are distributed through the nucleoplasm of vertebrate cells. Since speckles are not located at sites of co-transcriptional pre-mRNA splicing, which are associated closely with chromatin, they are thought to be storage regions for snRNPs and proteins involved in pre-mRNA splicing that are released into the nucleoplasm when required.

Promyelocytic Leukemia (PML) Nuclear Bodies The *PML* gene was originally discovered when chromosomal translocations within the gene were observed in the leukemic cells of patients with the rare disease promyelocytic leukemia (PML). When antibodies specific for the PML protein were used in immunofluorescence microscopy studies, the protein

was found to localize to ~10–30 roughly spherical regions 0.3–1 μm in diameter in the nuclei of mammalian cells. Multiple functions have been proposed for these PML nuclear bodies, but a consensus is emerging that they function as sites for the assembly and modification of protein complexes involved in DNA repair and the induction of apoptosis. For example, the important p53 tumor suppressor protein appears to be post-translationally modified by phosphorylation and acetylation in PML nuclear bodies in response to DNA damage, increasing its ability to activate the expression of DNA-damage response genes. PML nuclear bodies are also required for cellular defenses against DNA viruses that are induced by interferons, proteins secreted by virus-infected cells and T-lymphocytes involved in the immune response (see Chapter 23).

PML nuclear bodies are also sites of protein post-translational modification through the addition of a small, ubiquitin-like protein called *SUMO1* (small *u*biquitin-like *m*oiety-1), which can control the activity and subcellular localization of the modified protein. Many transcriptional activators are inhibited when they are sumoylated, and mutation of their site of sumoylation increases their activity in stimulating transcription. These observations indicate that PML nuclear bodies are involved in a mechanism of transcriptional repression that remains to be studied and thoroughly understood.

Nucleolar Functions in Addition to Ribosomal Subunit Synthesis The first nuclear bodies to be observed, the nucleoli, may have specialized regions of substructure that are dedicated to functions other than ribosome biogenesis. There is evidence that immature SRP ribonucleoprotein complexes involved in protein secretion and ER membrane insertion (Chapter 13) are assembled in nucleoli and then exported to the cytoplasm, where their final maturation takes place. The Cdc14 protein phosphatase that regulates processes in the final stages of mitosis is sequestered in nucleoli in yeast cells until chromosomes have been properly segregated into the bud (Chapter 19). Also, a tumor suppressor protein called ARF, which is involved in the regulation of the protein encoded by the most frequently mutated gene in human cancers, p53, is sequestered in nucleoli and released in response to DNA damage (Chapter 24). In addition, heterochromatin often forms on the surface of nucleoli (Figure 6-33), suggesting that proteins associated with nucleoli also participate in the formation of this repressing chromatin structure.

KEY CONCEPTS of Section 8.5

Processing of rRNA and tRNA

- A large precursor pre-rRNA (13.7 kb in humans) synthesized by RNA polymerase I undergoes cleavage, exonucleolytic digestion, and base modifications to yield mature 28S, 18S, and 5.8S rRNAs, which associate with ribosomal proteins into ribosomal subunits.

- Synthesis and processing of pre-rRNA occur in the nucleolus. The 5S rRNA component of the large ribosomal subunit is synthesized in the nucleoplasm by RNA polymerase III.
- Approximately 150 snoRNAs, associated with proteins in snoRNPs, base-pair with specific sites in pre-rRNA where they direct ribose methylation, modification of uridine to pseudouridine, and cleavage at specific sites during rRNA processing in the nucleolus.
- Group I and group II self-splicing introns and probably snRNAs in spliceosomes all function as ribozymes, or catalytically active RNA sequences, that carry out splicing by analogous transesterification reactions requiring bound Mg^{2+} ions (see Figure 8-41).
- Pre-tRNAs synthesized by RNA polymerase III in the nucleoplasm are processed by removal of the 5'-end sequence, addition of CCA to the 3' end, and modification of multiple internal bases (see Figure 8-42).
- Some pre-tRNAs contain a short intron that is removed by a protein-catalyzed mechanism distinct from the splicing of pre-mRNA and self-splicing introns.
- All species of RNA molecules are associated with proteins in various types of ribonucleoprotein particles, both in the nucleus and after export to the cytoplasm.
- Nuclear bodies are functionally specialized regions in the nucleus where interacting proteins form self-organized structures. Many of these, like the nucleolus, are regions of assembly of RNP complexes.

Perspectives for the Future

In this and the previous chapter, we have seen that in eukaryotic cells, mRNAs are synthesized and processed in the nucleus, transported through nuclear pore complexes to the cytoplasm, and then, in some cases, transported to specific areas of the cytoplasm before being translated by ribosomes. Each of these fundamental processes is carried out by complex macromolecular machines composed of scores of proteins and in many cases RNAs as well. The complexity of these macromolecular machines ensures accuracy in finding promoters and splice sites in the long length of DNA and RNA sequences and provides various avenues for regulating synthesis of a polypeptide chain. Much remains to be learned about the structure, operation, and regulation of such complex machines as spliceosomes and the cleavage/polyadenylation apparatus.

Recent examples of the regulation of pre-mRNA splicing raise the question of how extracellular signals might control such events, especially in the nervous system of vertebrates. A case in point is the remarkable situation in the chick inner ear, where multiple isoforms of the Ca^{2+} -activated K^+ channel called *Slo* are produced by alternative RNA splicing. Cell-cell interactions appear to inform cells of their position

in the cochlea, leading to alternative splicing of Slo pre-mRNA. The challenging task facing researchers is to discover how such cell-cell interactions regulate the activity of RNA-processing factors.

The mechanism of mRNP transport through nuclear pore complexes poses many intriguing questions. Future research will likely reveal additional activities of hnRNP and nuclear mRNP proteins and clarify their mechanisms of action. For instance, there is a small gene family encoding proteins homologous to the large subunit of the mRNA exporter. What are the functions of these related proteins? Do they participate in the transport of overlapping sets of mRNPs? Some hnRNP proteins contain nuclear-retention signals that prevent nuclear export when fused to hnRNP proteins with nuclear-export signals (NESs). How are these hnRNP proteins selectively removed from processed mRNAs in the nucleus, allowing the mRNAs to be transported to the cytoplasm?

The localization of certain mRNAs to specific subcellular locations is fundamental to the development of multicellular organisms. As we will discuss in Chapter 21, during development an individual cell frequently divides into daughter cells that function differently from each other. In the language of developmental biology, the two daughter cells are said to have different developmental fates. In many cases, this difference in developmental fate results from the localization of an mRNA to one region of the cell before mitosis so that after cell division, it is present in one daughter cell and not the other. Much exciting work remains to be done to fully understand the molecular mechanisms controlling mRNA localization that are critical for the normal development of multicellular organisms.

Some of the most exciting and unanticipated discoveries in molecular cell biology in recent years have concerned the existence and function of miRNAs and the process of RNA interference. RNA interference (RNAi) provides molecular cell biologists with a powerful method for studying gene function. The discovery of ~500 miRNAs in humans and other organisms suggests that multiple significant examples of translational control by this mechanism await characterization. Recent studies in *S. pombe* and plants link similar short nuclear RNAs to the control of DNA methylation and the formation of heterochromatin. Will similar processes control gene expression through the assembly of heterochromatin in humans and other animals? What other regulatory processes might be directed by other kinds of small RNAs? Since control by these mechanisms depends on base pairing between miRNAs and target mRNAs or genes, genomic and bioinformatic methods will probably suggest genes that may be controlled by these mechanisms. What other processes in addition to translation control, mRNA degradation, and heterochromatin assembly might be controlled by miRNAs?

These are just a few of the fascinating questions concerning RNA processing, post-transcriptional control, and nuclear transport that will challenge molecular cell biologists in the coming decades. The astounding discoveries of entirely unanticipated mechanisms of gene control by miRNAs remind us that many more surprises are likely in the future.

Key Terms

5' cap 349	poly(A) tail 358
alternative splicing 361	pre-mRNA 349
cleavage/polyadenylation complex 358	pre-rRNA 385
cross-exon recognition complex 356	ribozyme 390
Dicer 371	RNA editing 364
Drosha 371	RNA-induced silencing complex (RISC) 371
exosome 359	RNA interference (RNAi) 373
FG-nucleoporins 365	RNA splicing 348
group I introns 357	short interfering RNAs (siRNA) 346
group II introns 357	siRNA knockdown 374
iron-response element-binding protein (IRE-BP) 379	small nuclear RNAs (snRNAs) 352
micro RNAs (miRNAs) 370	small nucleolar RNAs (snoRNAs) 386
mRNA surveillance 380	spliceosome 353
mRNP exporter 365	SR proteins 356
nuclear pore complex (NPC) 365	

Review the Concepts

1. Describe three types of post-transcriptional regulation of protein-coding genes.
2. True or False? The CTD is responsible for mRNA-processing steps that are specific for mRNA, and not other forms of RNA. Explain why you chose true or false.
3. There are a number of conserved sequences found in an mRNA which dictate where splicing occurs. Where are these sequences found relative to the exon/intron junctions? What is the significance of these sequences in the splicing process? One of these important regions is the branch point A found in the intron. What is the role of the branch point A in the splicing process, and can this be accomplished with the OH group on either the 2' or the 3' carbon?
4. What is the difference between hnRNAs, snRNAs, miRNAs, siRNAs, and snoRNAs?
5. What are the mechanistic similarities between group II intron self-splicing and spliceosomal splicing? What is the evidence that there may be an evolutionary relationship between the two?
6. You obtain the sequence of a gene containing 10 exons, 9 introns, and a 3' UTR containing a polyadenylation consensus sequence. The fifth intron also contains a polyadenylation site. To test whether both polyadenylation sites are used, you isolate mRNA and find a longer transcript from muscle tissue and a shorter transcript from all other tissues. Speculate about the mechanism involved in the production of these different transcripts.

7. RNA editing is a common process occurring in the mitochondria of trypanosomes and plants, in chloroplasts, and in rare cases in higher eukaryotes. What is RNA editing, and what benefit does it demonstrate in the documented example of apoB in humans?

8. As DNA is found in the nucleus, transcription is a nuclear-localized process. Ribosomes responsible for protein synthesis are found in the cytoplasm. Why is hnRNP trafficking to the cytoplasm restricted to the nuclear pore complexes? How do the FG-repeats of the nuclear pore complexes act as a specificity barrier in nuclear transport?

9. A protein complex in the nucleus is responsible for transporting mRNA molecules into the cytoplasm. Describe the proteins that form this exporter. What two protein groups are likely behind the mechanism involved in the directional movement of the mRNP and exporter into the cytosol.

10. RNA knockdown has become a powerful tool in the arsenal of methods to deregulate gene expression. Briefly describe how gene expression can be knocked down. What effect would introducing siRNAs to TSC1 have on human cells?

11. Speculate about why plants deficient in Dicer activity show increased sensitivity to infection by RNA viruses.

12. mRNA stability is a key regulator of protein levels in a cell. Briefly describe the three mRNA degradation pathways. A yeast cell has a mutation in the DCP1 gene, resulting in decreased uncapping activity. Would you expect to see a change in the P bodies found in this mutant cell?

13. mRNA localization now appears to be a common phenomenon. What benefit does mRNA localization have for a cell? What is the evidence that some mRNAs are directed to accumulate in specific subcellular locations?

Analyze the Data

Most humans are infected with herpes simplex virus-1 (HSV-1), the causative agent of cold sores. The HSV-1 genome comprises about 100 genes, most of which are expressed in infected host cells at the site of oral sores. The infectious process involves replication of viral DNA, transcription and translation of viral genes, assembly of new viral particles, and death of the host cell as the viral progeny are released. Unlike most other types of viruses, herpesvirus also has a latent phase, in which the virus remains hidden in neurons. These latently infected neurons are the source of active infections, causing cold sores when latency is overcome.

Interestingly, only a single viral transcript is expressed during latency. This transcript, *LAT* (latency-associated transcript), does not encode a protein, and neurons infected with mutant HSV-1 lacking the *LAT* gene undergo cell death by apoptosis at a rate twice that of cells infected with wild-type HSV-1. To determine if *LAT* functions to block apoptosis by encoding a miRNA, the following studies were done (see Gupta et al., 2006, *Nature* 442:82–85).

a. A cell line was transfected (a process in which foreign DNA is inserted into a cell) with an expression vector that

expresses a Pst-Mlu fragment of the *LAT* gene (see diagram in part b). The percentage of these transfected cells that then underwent drug-induced cell death was compared to that of control cells. The experiment was repeated in cells in which Dicer expression was knocked down using Dicer siRNA. The data obtained are shown in the graph below. What conclusions can be drawn from these data? Why did the scientists who conducted this study examine the effects of silencing Dicer?

b. Cells were transfected with an expression vector expressing the Pst-Mlu fragment of the *LAT* gene from which the region between the two Sty restriction sites was deleted (DSty; diagram below). When these cells were induced to undergo apoptosis, they died at the same rate as did non-transfected cells. In additional studies, cells were transfected with an expression vector expressing the Sty-Sty region of the *LAT* gene. These cells exhibited the same resistance to apoptosis as did cells transfected with the Pst-Mlu fragment. What can be deduced from these findings about the region of the *LAT* gene required to protect cells from apoptosis?

c. RNA encoded within the Sty-Sty region is predicted to form a stem loop (see diagram in part b). Northern blot analysis was performed on total-cell RNA isolated from control cells (mock), cells infected with wild-type HSV-1, cells infected with an HSV-1 deletion mutant from which the sequence between the two Sty sites in the *LAT* gene was deleted (DSty), and cells infected with a rescued DSty virus into which the deleted region was re-inserted into the viral genome (StyR). The probe used for the Northern blot was the labeled 3' stem region of the *LAT* RNA in the Sty-Sty region, as diagrammed in part (b). The RNAs recognized by this probe were either ~55 nucleotides or 20 nucleotides, as shown in

the Northern blot below. Why were two different-sized RNAs detected? When a second probe was used that was the labeled 5' stem region of the RNA sequence shown in part (b), only the ~55-nucleotide RNA was detected. What can you deduce about the processing of RNA expressed from the *LAT* gene? What enzyme likely produced the ~55-nucleotide RNA? In what part of the cell? What enzyme likely produced the 20-nucleotide RNA? In what part of the cell?

d. TGF- β mRNA encodes a protein, transforming growth factor β , that inhibits cell growth and induces apoptosis. The 3' untranslated region (3' UTR) of TGF- β mRNA can form an imperfect duplex with miRNA encoded by the 5' stem region of the *LAT* Sty-Sty domain (miR-LAT), as shown below. In what way might the expression levels of TGF- β differ in cells infected with wild-type HSV-1 compared to uninfected cells? What can you infer about latent HSV-1 infections from these studies?

Fluorescence microscopy shows the location of DNA and multiple proteins within the same cell. Here fluorescent tagging and staining techniques using different fluorescent molecules reveal the cytoskeletal proteins α -tubulin (green) and actin (red), DNA (blue), the Golgi complex (yellow), and mitochondria (purple). The images along the top are false-colored images of each structure stained individually. The larger image merges these separate images to depict the full cell. [From B. N. G. Giepmans, et al., 2006, *Science* **312**:217.]

It is difficult to believe that 400 years ago, it was not yet known that all living things are made of cells. In 1655, Robert Hooke used a primitive microscope to examine a piece of cork and saw an orderly arrangement of rectangles—the walls of the dead plant cells—that reminded him of monk cells in a monastery, so he coined the term *cells*. Shortly after this, Antonie van Leeuwenhoek described the microorganisms that he saw in his simple microscope, the first description of living cells. Two hundred years later, Matthias Schleiden and Theodore Schwann observed that individual cells constitute the fundamental unit of life in a variety of plants, animals, and single-celled organisms. Collectively, these were some of the greatest discoveries in biology and posed the question of how cells are organized and function. However, many technical constraints hamper studies of cells in intact animals and plants. One alternative is the use of intact organs that are removed from animals and treated to maintain their physiologic integrity and function. However, the organization of

Culturing, Visualizing, and Perturbing Cells

organs, even isolated ones, is sufficiently complex to pose numerous problems for research. Thus molecular cell biologists often conduct experimental studies on cells isolated from an organism. In Section 9.1, we learn how to maintain and grow diverse cell types and how to isolate specific types of cells from complex mixtures. However, cells in culture are not in their native setting, so we discuss how researchers are now growing and examining cells in three-dimensional environments to more closely mimic their situation in an animal.

In many cases, isolated cells can be maintained in the laboratory under conditions that permit their survival and growth, a procedure known as *culturing*. Cultured cells have several advantages over intact organisms for cell biology research. Cells of a single specific type can be grown in culture, experimental conditions can be better controlled, and in many cases a single cell can be readily grown into a colony of many identical cells. The resulting strain of cells, which is genetically homogeneous, is called a *clone*.

Discoveries about cellular organization have been intimately tied with developments in both light and electron microscopy. This is as true today as it was 400 years ago. Light microscopy initially revealed the beautiful internal organization of cells, and today highly sophisticated microscopes are continually being improved to probe deeper and deeper to reveal the molecular mechanism by which cells function. In Section 9.2, we discuss light microscopy and the different technologies available, long-standing but still valuable methods, and then trace through several clever methods that have been developed since, culminating with the newest, cutting-edge technologies. A major advance came in the 1960s and 1970s with the development of *immunofluorescence microscopy* to allow the localization of specific proteins within fixed cells, thus providing a static image of their location, as illustrated in the opening figure. Such studies led to the important concept that the membranes and interior spaces of each type of organelle contain a distinctive group of proteins that are essential for the organelle to carry out its unique functions. A major advance came in the mid-1990s with the simple idea of expressing *chimeric proteins*—consisting of a protein of interest covalently linked to a naturally fluorescent protein—to enable biologists to visualize the movements of individual proteins in live cells. Suddenly, the dynamic nature of cells could be appreciated, which changed the view of cells from the previously available static images. In addition, it presented a technological challenge—the more sensitive a microscope could be made to detect the fluorescent protein, the more information the investigator could glean from the data. It also opened up the development of fluorescent techniques to monitor protein-protein interactions in living cells, as well as a myriad of other sophisticated molecular technologies, some of which we also discuss in this section.

Despite the amazing developments in light microscopy, visible light provides too low a resolution to examine cells in ultrastructural detail. The electron microscope gives a much higher resolution, but the technology generally requires that the cell be fixed and sectioned and so all cell movements are frozen in time. Electron microscopy also allows investigators to examine the structure of macromolecular complexes or single macromolecules. In Section 9.3, we outline the various approaches for preparing specimens for observation in the electron microscope and describe the type of information that can be derived from them.

Light and electron microscopy revealed that all eukaryotic cells—whether of fungal, plant, or animal origin—contain a similar repertoire of membrane-limited compartments termed **organelles**. In Section 9.4, we provide a simple introduction to the basic structure and function of the major organelles in animal and plant cells, as a prelude to their detailed description in subsequent chapters. In parallel with the developments in microscopy, subcellular fractionation methods were developed that have enabled cell biologists to isolate individual organelles to a high degree of purity. These techniques, also detailed in Section 9.4, continue to provide important information about the protein composition and biochemical function of organelles.

Microscopy and organelle characterization are inherently descriptive technologies. How can one investigate the molecular mechanisms underlying cell biological processes? If we want to understand how a car works, we can explore the effects of removing or interfering with individual components to see what happens. This, of course, is in principle the concept of genetic analysis we described in Chapter 5: how interfering with a specific component can be used to explore its function. In Section 9.5, we describe how small molecules that interfere with the function of specific proteins can also be used to dissect cellular processes. Finally, we describe how the discovery of small interfering RNAs that target specific mRNAs for destruction has been exploited to suppress expression of specific proteins in both cultured cells and whole animals to expand and complement the use of classical genetics in the analysis of biological processes.

9.1 Growing Cells in Culture

The study of cells is greatly facilitated by growing them in culture, where they can be examined by microscopy and subjected to specific treatments under controlled conditions. It is generally quite easy to grow unicellular bacterial, fungal, or protist cells; for example, by placing them in a rich medium that supports their growth. However, animal cells come from multicellular organisms, making it more difficult to culture single or small groups of cells. In this section, we discuss how animal cells are grown in culture and how different cell types can be purified for study.

Culture of Animal Cells Requires Nutrient-Rich Media and Special Solid Surfaces

To permit the survival and normal function of cultured tissues or cells, the temperature, pH, ionic strength, and access to essential nutrients must simulate as closely as possible the conditions within an intact organism. Isolated animal cells are typically placed in a nutrient-rich liquid, called the culture medium, within specially coated plastic dishes or flasks. The cultures are kept in incubators in which the temperature, atmosphere, and humidity can be controlled. To reduce the chances of bacterial or fungal contamination, antibiotics are often added to the culture medium. To further guard against contamination, investigators usually transfer cells between dishes, add reagents to the culture medium, and otherwise manipulate the specimens within special sterile cabinets containing circulating air that is filtered to remove microorganisms and other airborne contaminants.

Media for culturing animal cells must supply the nine amino acids (phenylalanine, valine, threonine, tryptophan, isoleucine, methionine, leucine, lysine, and histidine) that cannot be synthesized by adult vertebrate animal cells. In addition, most cultured cells require three other amino acids (cysteine, tyrosine, and arginine) that are synthesized only by specialized cells in intact animals, as well as glutamine,

which serves as a nitrogen source. The other necessary components of a medium for culturing animal cells are vitamins, various salts, fatty acids, glucose, and serum—the fluid remaining after the noncellular part of blood (plasma) has been allowed to clot. Serum contains various protein factors that are needed for the proliferation of mammalian cells in culture, including the polypeptide hormone insulin; transferrin, which supplies iron in a bioaccessible form; and numerous growth factors. In addition, certain cell types require specialized protein growth factors not present in serum. For instance, progenitors of red blood cells require erythropoietin, and T lymphocytes require interleukin 2 (see Chapter 16). A few mammalian cell types can be grown in a chemically defined, serum-free medium containing amino acids, glucose, vitamins, and salts plus certain trace minerals, specific protein growth factors, and other components.

Unlike bacterial and yeast cells, which can be grown in suspension, most animal cell types will grow only attached to a solid surface. This requirement highlights the importance of cell-surface proteins, called **cell-adhesion molecules (CAMs)**, that cells use to bind to adjacent cells and to components of the extracellular matrix (ECM) such as collagen or fibronectin (see Chapter 20). These ECM proteins coat the solid surface (usually glass or plastic) and either come from the serum or are secreted by the cells in culture. A single cell cultured on a glass or a plastic dish proliferates to form a visible mass, or *colony*, containing thousands of genetically identical cells in 4 to 14 days, depending on the growth rate. Some specialized blood cells and tumor cells can be maintained or grown in suspension as single cells.

Primary Cell Cultures and Cell Strains Have a Finite Life Span

Normal animal tissues (e.g., skin, kidney, liver) or whole embryos are commonly used to establish *primary cell cultures*. To prepare individual tissue cells for a primary culture, the cell-cell and cell-matrix interactions must be broken. To do so, tissue fragments are treated with a combination of a protease (e.g., trypsin, the collagen-hydrolyzing enzyme collagenase, or both) and a divalent cation chelator (e.g., EDTA) that depletes the medium of free Ca^{2+} . Many cell-adhesion molecules require calcium and are thus inactivated when calcium is removed; other cell-adhesion molecules that are not calcium dependent need to be proteolyzed for the cells to separate. The released cells are then placed in dishes in a nutrient-rich, serum-supplemented medium, where they can adhere to the surface and to one another. The same protease-chelator solution is used to remove adherent cells from a culture dish for biochemical studies or subculturing (transfer to another dish).

Fibroblasts are the predominant cells in connective tissue and normally produce ECM components such as collagen that bind to cell-adhesion molecules, thereby anchoring cells to a surface. In culture, fibroblasts usually divide more rapidly than other cells from a tissue, eventually becoming the predominant cell type in a primary culture unless special precautions are taken to remove them when isolating other types of cells.

When cells removed from an embryo or an adult animal are cultured, most of the adherent cells will divide a finite number of times and then cease growing (cell senescence). For instance, human fetal fibroblasts divide about 50 times before they cease growth (Figure 9-1a). Starting with 10^6 cells, 50 doublings has the potential to produce $10^6 \times 2^{50}$, or more than 10^{20} cells, which is equivalent to the weight of about 1000 people. Normally, only a very small fraction of these cells are used in any one experiment. Thus, even though its lifetime is limited, a single culture, if carefully maintained, can be studied through many cell generations. Such a lineage of cells originating from one initial primary culture is called a **cell strain**.

One important exception to the finite life of normal cells is the *embryonic stem cell*, which, as its name implies, is

FIGURE 9-1 Stages in the establishment of a cell culture.

(a) When cells isolated from human tissue are initially cultured, some cells die and others (mainly fibroblasts) start to grow; overall, the growth rate increases (phase I). If the remaining cells are harvested, diluted, and replated into dishes again and again, the cell strain continues to divide at a constant rate for about 50 cell generations (phase II), after which the growth rate falls rapidly. In the ensuing period (phase III), all the cells in the culture stop growing (senescence). (b) In a culture prepared from mouse or other rodent cells, initial cell death (not shown) is coupled with the emergence of healthy growing cells. As these dividing cells are diluted and allowed to continue growth, they soon begin to lose growth potential, and most stop growing (i.e., the culture goes into senescence). Very rare cells undergo oncogenic mutations that allow them to survive and continue dividing until their progeny overgrow the culture. These cells constitute a cell line, which will grow indefinitely if it is appropriately diluted and fed with nutrients. Such cells are said to be immortal.

derived from an embryo and will divide and give rise to all tissues during development. As we discuss in Chapter 21, embryonic stem cells can be cultured indefinitely under the appropriate conditions.

Research with cell strains is simplified by the ability to freeze and successfully thaw them at a later time for experimental analysis. Cell strains can be frozen in a state of suspended animation and stored for extended periods at liquid nitrogen temperature, provided that a preservative that prevents the formation of damaging ice crystals is used. Although not all cells survive thawing, many do survive and resume growth.

Transformed Cells Can Grow Indefinitely in Culture

To be able to clone individual cells, modify cell behavior, or select mutants, biologists often want to maintain cell cultures for many more than 50 doublings. Such prolonged growth is exhibited by cells derived from some tumors. In addition, rare cells in a population of primary cells may undergo spontaneous oncogenic mutations, leading to oncogenic **transformation** (see Chapter 24). Such cells, said to be oncogenically transformed or simply *transformed*, are able to grow indefinitely. A culture of cells with an indefinite life span is considered immortal and is called a **cell line**.

Primary cell cultures of normal rodent cells commonly undergo spontaneous transformation into a cell line. After rodent cells are grown in culture for several generations, the culture goes into senescence (Figure 9-1b). During this pe-

riod, most of the cells stop growing, but often a rapidly dividing transformed cell arises spontaneously and takes over, or overgrows, the culture. A cell line derived from such a transformed variant will grow indefinitely if provided with the necessary nutrients. In contrast to rodent cells, normal human cells rarely undergo spontaneous transformation into a cell line. The HeLa cell line, the first human cell line established, was originally obtained in 1952 from a malignant tumor (carcinoma) of the uterine cervix. Other human cell lines are often derived from cancers, and others have been rendered immortal by transforming them to express oncogenes.

Regardless of the source, cells in immortalized lines often have chromosomes with abnormal DNA sequences. In addition, the number of chromosomes in such cells is usually greater than that in the normal cell from which they arose, and the chromosome number changes as the cells continue to divide in culture. A noteworthy exception is the Chinese hamster ovary (CHO) line and its derivatives, which have fewer chromosomes than their hamster progenitors. Cells with an abnormal number of chromosomes are said to be *aneuploid*.

Flow Cytometry Separates Different Cell Types

Some cell types differ sufficiently in density that they can be separated on the basis of this physical property. White blood cells (leukocytes) and red blood cells (erythrocytes), for instance, have very different densities because erythrocytes have no nucleus; thus these cells can be separated by equilibrium

FIGURE 9-2 Fluorescence-activated cell sorter (FACS) separates cells that are labeled differentially with a fluorescent reagent. Step 1: A concentrated suspension of labeled cells is mixed with a buffer (the sheath fluid) so that the cells pass single-file through a laser light beam.

Step 2: Both the fluorescent light emitted and the light scattered by each cell are measured; from measurements of the scattered light, the size and shape of the cell can be determined. Step 3: The suspension is then forced through a nozzle, which forms tiny droplets containing at most a single cell. At the time of formation at the nozzle tip, each droplet containing a cell is given a negative electric charge proportional to the fluorescence of that cell determined from the earlier measurement.

Step 4: Droplets now pass through an electric field, so that those with no charge are discarded, whereas those with different electric charges are separated and collected. Because it takes only milliseconds to sort each droplet, as many as 10 million cells per hour can pass through the machine. [Adapted from D. R. Parks and L. A. Herzenberg, 1982, *Meth. Cell Biol.* 26:283.]

density centrifugation (described in Section 9.4). Because most cell types cannot be differentiated so easily, other techniques such as flow cytometry must be used to separate them.

To identify one type of cell from a complex mixture, it is necessary to have some way to mark and then sort out the desired cells. Different cell types often express different molecules on their cell surface. If a particular surface molecule is only expressed on the desired cell type, this can be used to mark those cells. The cell mixture can be incubated with a fluorescent dye linked to an antibody to the specific cell-surface molecule, thus rendering just the desired cells fluorescent. The cells can be analyzed in a *flow cytometer*. This machine flows cells past a laser beam that measures the light that they scatter and the fluorescence that they emit; thus it can quantify the numbers of cells of the desired type from a mixture. A *fluorescence-activated cell sorter (FACS)*, which is based on flow cytometry, can both analyze the cells and select one or a few cells from thousands of others and sort them into a separate culture dish (Figure 9-2). To sort the cells, their concentration has to be adjusted so that the tiny droplets that the FACS machine makes and analyzes contain only one cell each. A stream of droplets is analyzed for fluorescence, and those that have the desired signal are sorted away from those that do not. Having been sorted from other cells, the selected cells can be grown in culture.

The FACS procedure is commonly used to purify the different types of white blood cells, each of which bears on its surface one or more distinctive proteins and so will bind monoclonal antibodies specific for that protein. Only the T cells of the immune system, for instance, have both CD3 and Thy1.2 proteins on their surfaces. The presence of these surface proteins allows T cells to be separated easily from other types of blood cells or spleen cells (Figure 9-3).

Other uses of flow cytometry include the measurement of a cell's DNA and RNA content and the determination of its general shape and size. The FACS can make simultaneous measurements of the size of a cell (from the amount of scattered light) and the amount of DNA that it contains (from the amount of fluorescence emitted from a DNA-binding dye). Measurements of the DNA content of individual cells are used to follow replication of DNA as the cells progress through the cell cycle (see Chapter 19).

An alternative method for separating specific types of cells uses small magnetic beads coupled to antibodies for the specific surface molecule. For example, to isolate T cells, the beads are coated with a monoclonal antibody specific for a surface protein such as CD3 or Thy1.2. Only cells with these proteins will stick to the beads and can be recovered from the preparation by adhesion to a small magnet on the side of the test tube.

Growth of Cells in Two-Dimensional and Three-Dimensional Culture Mimics the In Vivo Environment

While much has been learned using cells grown on a plastic or glass surface, these surfaces are far removed from cells' normal tissue environment. As detailed in Chapter 20, many

EXPERIMENTAL FIGURE 9-3 T cells bound to fluorescence-tagged antibodies to two cell-surface proteins are separated from other white blood cells by FACS. Spleen cells from a mouse were treated with a red fluorescent monoclonal antibody specific for the CD3 cell-surface protein and with a green fluorescent monoclonal antibody specific for a second cell-surface protein, Thy1.2. As the cells were passed through a FACS machine, the intensity of the green and red fluorescence emitted by each cell was recorded. Each dot represents a single cell. This plot of the green fluorescence (vertical axis) versus red fluorescence (horizontal axis) for thousands of spleen cells shows that about half of them—the T cells—express both CD3 and Thy1.2 proteins on their surfaces (upper-right quadrant). The remaining cells, which exhibit low fluorescence (lower-left quadrant), express only background levels of these proteins and are other types of white blood cells. Note the logarithmic scale on both axes. [Courtesy of Chengcheng Zhang, Whitehead Institute.]

cell types function only when closely linked to other cells. Key examples are the sheet-like layers of epithelial tissue, called **epithelia** (singular, **epithelium**), which cover the external and internal surfaces of organs. Typically, the distinct surfaces of a polarized epithelial cell are called the **apical** (top), **basal** (base or bottom), and **lateral** (side) surfaces (see Figure 20-10). The basal surface usually contacts an underlying extracellular matrix called the **basal lamina**, whose composition and function are discussed in Section 20.3. Epithelial cells often function to transport specific classes of molecules across the epithelial sheet; for example, the epithelial lining of the intestine transports nutrients into the cell through the apical surface and out toward the bloodstream across the basolateral surface. When grown on plastic or glass, epithelial cells cannot easily perform this function. Therefore, special containers have been designed with a porous surface that acts as the basal lamina to which epithelial cells attach and form a uniform two-dimensional sheet (Figure 9-4). A commonly used cultured cell line derived from dog kidney epithelium is called *Madin-Darby canine kidney (MDCK) cells* and is often used to study the formation and function of epithelial sheets.

FIGURE 9-4 Madin-Darby canine kidney (MDCK) cells grown in specialized containers provide a useful experimental system for studying epithelial cells. MDCK cells form a polarized epithelium when grown on a porous membrane filter coated on one side with collagen and other components of the basal lamina. With the use of the special culture dish shown here, the medium on each side of the filter (apical and basal sides of the monolayer) can be experimentally manipulated and the movement of molecules across the layer monitored. Several cell junctions that interconnect the cells form only if the growth medium contains sufficient Ca^{2+} .

However, even a two-dimensional sheet often does not allow cells to fully mimic behavior in their normal environment. Methods have now been developed to grow cells in three dimensions by providing a support infiltrated with components of the extracellular matrix. If MDCK cells are cultured under appropriate conditions, they will form a tubular sheet mimicking a tubular organ or the duct of the secretory gland. In these three-dimensional structures, the apical aspect of the epithelial sheet lines the lumen, whereas the basal side of each cell is in contact with the extracellular matrix (Figure 9-5).

Hybrid Cells Called Hybridomas Produce Abundant Monoclonal Antibodies

In addition to serving as research models for studies on cell function, cultured cells can be converted into “factories” for producing specific proteins. In Chapter 5, we described how

introducing genes encoding insulin, growth factors, and other therapeutically useful proteins into bacterial or eukaryotic cells can be used to express and recover these proteins (see Figures 5-31 and 5-32). Here we consider the use of special cultured cells to generate monoclonal antibodies, which are experimental tools widely used in many aspects of cell biological research. Increasingly, they are being used for diagnostic and therapeutic purposes in medicine, as we discuss in later chapters.

To understand the challenge of generating monoclonal antibodies, we need to briefly review how mammals produce antibodies; more detail is provided in Chapter 23. Recall that antibodies are proteins secreted by white blood cells that bind with high affinity to their antigen (see Figure 3-19). Each normal antibody-producing B lymphocyte in a mammal is capable

EXPERIMENTAL FIGURE 9-5 MDCK cells can form cysts in culture. (a) MDCK cells grown in a supported extracellular matrix will form groups of cells that polarize to form a spherical single layer of cells with a lumen in the middle, called a cyst. (b) By examining the localization of proteins found in the apical (red) and basolateral

membranes (green), these cells can be seen to be fully polarized with the apical side facing the lumen, which recapitulates their organization in the kidney tubules from which they are derived. The nuclear DNA is stained blue. (Parts (a) and (b) from D. M. Bryant et al., 2010, *Nat. Cell Biol.* 12:1035.)

of producing a single type of antibody that can bind to a particular **determinant** or **epitope** on an antigen molecule. An epitope is generally a small region on the antigen, for example, consisting of just a few amino acids. If an animal is injected with an antigen, the B lymphocytes that make antibodies recognizing that antigen are stimulated to grow and secrete the antibodies. Each antigen-activated B lymphocyte forms a clone of cells in the spleen or lymph nodes, with each cell of the clone producing the identical antibody—that is, a *monoclonal antibody*. Because most natural antigens contain multiple epitopes, exposure of an animal to an antigen usually stimulates the formation of multiple different B-lymphocyte clones, each producing a different specific antibody. The resulting mixture of antibodies from the many B-lymphocyte clones that recognize different epitopes on the same antigen is said to be *polyclonal*. Such polyclonal antibodies circulate in the blood and can be isolated as a group.

Although polyclonal antibodies are very useful, monoclonal antibodies are suitable for many types of experiments and medical applications when you need a reagent that binds to just one site on a protein; for example, one that competes with a ligand on a cell-surface receptor. Unfortunately, the biochemical purification of any one type of monoclonal antibody from blood is not feasible for two main reasons: the concentration of any given antibody is quite low, and all antibodies have the same basic molecular architecture (see Figure 3-19).

To produce and then purify monoclonal antibodies, one first needs to be able to grow the appropriate B-lymphocyte clone. However, primary cultures of normal B lymphocytes are of limited usefulness for the production of monoclonal antibodies because they have a limited life span. Thus the first step in producing a monoclonal antibody is to generate immortal, antibody-producing cells (Figure 9-6). This immortality is achieved by fusing normal B lymphocytes from an immunized animal with transformed, immortal lymphocytes called *myeloma cells* that themselves synthesize neither the heavy nor the light polypeptides that constitute all antibodies (see Figure 3-19). Treatment with certain viral glycoproteins or the chemical polyethylene glycol promotes the plasma membranes of two cells to fuse, allowing their cytosols and organelles to intermingle. Some of the fused cells undergo division, and their nuclei eventually coalesce, producing viable *hybrid cells* with a single nucleus that contains chromosomes from both “parents.” The fusion of two cells that are genetically different can yield a hybrid cell with novel characteristics. For instance, the fusion of a myeloma cell with a normal antibody-producing cell from a rat or mouse spleen yields a hybrid that proliferates into a clone called a **hybridoma**. Like myeloma cells, hybridoma cells grow rapidly and are immortal. Each hybridoma produces the monoclonal antibody encoded by its B-lymphocyte parent.

The second step in this procedure for producing monoclonal antibody is to separate, or select, the hybridoma cells from the unfused parental cells and the self-fused cells generated by the fusion reaction. This selection is usually performed by incubating the mixture of cells in a special culture medium, called *selection medium*, that permits the growth of only the

FIGURE 9-6 Use of cell fusion and selection to obtain hybridomas producing monoclonal antibody to a specific protein.

Step 1: Immortal myeloma cells that cannot synthesize purines under special conditions because they lack thymidine kinase are fused with normal antibody-producing spleen cells from an animal that was immunized with antigen X. **Step 2:** When cultured in/on a special selective medium, unfused and self-fused cells do not grow: the mutant myeloma cells do not grow because the selective medium does not contain purines and the spleen cells because they have a limited life span in culture. Thus only fused cells formed from a myeloma cell and a spleen cell survive in the special medium, proliferating into clones called hybridomas. Each hybridoma produces a single antibody. **Step 3:** Testing of individual clones identifies those that recognize antigen X. After a hybridoma that produces a desired antibody has been identified, the clone can be cultured to yield large amounts of that antibody.

hybridoma cells because of their novel characteristics. The myeloma cells used for the fusion carry a mutation that blocks a metabolic pathway, so a selection medium can be used that is lethal to them and not their lymphocyte fusion partners that do not have the mutation. In the immortal hybrid cells, the functional gene from the lymphocyte can supply the missing gene product, and thus the hybridoma cells will be able to grow in the selection medium. Because the lymphocytes used in the fusion are not immortalized, only the hybridoma cells will proliferate rapidly in the selection medium and so can be readily isolated from the initial mixture of cells. Finally, each selected hybridoma clone is then tested for the production of the desired antibody; any clone producing that antibody is then grown in large cultures, from which a substantial quantity of pure monoclonal antibody can be obtained.

Monoclonal antibodies have become very valuable reagents as specific research tools. They are commonly employed in affinity chromatography to isolate and purify proteins from complex mixtures (see Figure 3-38c). As we discuss later in this chapter, they can also be employed in immunofluorescence microscopy to bind and so locate a particular protein within cells. They can also be used to identify specific proteins in cell fractions with the use of immunoblotting (see Figure 3-39). Monoclonal antibodies have become important diagnostic and therapeutic tools in medicine; for example, monoclonal antibodies that bind to and inactivate toxins secreted by bacterial pathogens are used to treat diseases. Other monoclonal antibodies are specific for cell-surface proteins expressed by certain types of tumor cells. Several of these anti-tumor antibodies are widely used in cancer therapy, including monoclonal antibody against a mutant form of the Her2 receptor that is overexpressed in some breast cancers (see Figure 16-7).

KEY CONCEPTS of Section 9.1

Growing Cells in Culture

- Animal cells have to be grown in culture under conditions that mimic their natural environment, which generally requires them to be supplied with necessary amino acids and growth factor supplements.
- Most animal cells need to adhere to a solid surface to grow.
- Primary cells—those isolated directly from tissue—have a finite life span.
- Transformed cells, like cells derived from tumors, can grow indefinitely in culture.
- Cells that can be grown indefinitely are called a cell line.
- Many cell lines are aneuploid, having a different number of chromosomes than the parent animal from which they were derived.
- Different cells express different marker proteins on their cell surface, which can be used to distinguish them.

- Using fluorescent antibodies to cell-surface molecules, a machine called a fluorescent-activated cell sorter can sort out cells with different surface markers.
- To mimic growth in tissues, epithelial cells are often grown in special containers to mimic their functional polarity. Cells can also be grown in three-dimensional matrices to more accurately reflect their normal environment.
- Monoclonal antibodies, reagents that bind one epitope on an antigen, can be secreted by cultured cells called hybridomas. These hybrid cells are made by fusing an antibody-producing B-cell with an immortalized myeloma cell and then identifying those clones that produce the antibody. Monoclonal antibodies are important for basic research and as therapeutic agents.

9.2 Light Microscopy: Exploring Cell Structure and Visualizing Proteins Within Cells

The existence of the cellular basis of life was first appreciated using primitive light microscopes. Since then, progress in cell biology has paralleled and often been driven by technological advances in light microscopy (Figure 9-7). Here we discuss each of these major developments and how they advanced the study of cellular processes. First we describe basic uses of a light microscope to observe unstained cells and structures. Next we describe the development of fluorescence microscopy and its use to localize specific proteins in fixed cells. By using molecular genetic approaches to express a fusion between a protein of interest and a naturally fluorescent protein, it is possible to follow the localization of specific proteins in living cells—an ability that revealed how dynamic the organization of living cells is. In parallel with these advances in specimen preparation, optical advances were being made to enhance and sharpen the images provided by fluorescence microscopy to reveal cellular structure in unprecedented clarity. Many specialized technologies have emerged from these advances, and we describe some of the more important ones.

The Resolution of the Light Microscope Is About 0.2 μm

All microscopes produce a magnified image of a small object, but the nature of the image depends on the type of microscope employed and on the way the specimen is prepared. The compound microscope, used in conventional *bright-field light microscopy*, contains several lenses that magnify the image of a specimen under study (Figure 9-8a). The total magnification is a product of the magnification of the individual lenses: if the *objective lens*, the lens closest to the specimen, magnifies 100-fold (a 100 $\times$ lens, the maximum usually employed) and the *projection lens*, sometimes called

FIGURE 9-7 Development of the light microscope. (a) Early microscopes, like ones used by Robert Hooke in the 1660s, used lenses or a mirror to illuminate the specimen. (b) Optics in general and light microscopes in particular developed enormously during the nineteenth century, and by the middle of the twentieth century highly

sophisticated microscopes limited only by the resolution of light were common. (c) In the second half of the twentieth century, fluorescence microscopy and digital imaging together with confocal techniques were developed to yield the versatile microscopes of today. [Part (a) SSPL via Getty Images; part (b) courtesy of Carl Zeiss Archive; part (c) Zeiss.com.]

the ocular or eyepiece, magnifies 10-fold, the final magnification recorded by the human eye or on a camera will be 1000-fold.

However, the most important property of any microscope is not its magnification but its resolving power, or **resolution**—the ability to distinguish between two very closely positioned objects. Merely enlarging the image of a specimen accomplishes nothing if the image is blurred. The resolution of a microscope lens is numerically equivalent to D , the minimum distance between two distinguishable objects. The smaller the value of D , the better the resolution. The value of D is given by the equation

$$D = \frac{0.61\lambda}{N \sin\alpha} \quad (9-1)$$

where α is the angular aperture, or half-angle, of the cone of light entering the objective lens from the specimen (see Figure 9-8a), N is the refractive index of the medium between the specimen and the objective lens (i.e., the relative velocity of light in the medium compared with the velocity in air), and λ is the wavelength of the incident light. Resolution is improved by using shorter wavelengths of light (decreasing the value of λ) or gathering more light (increasing either N or α). Lenses for high-resolution microscopy are designed to work with oil between the lens and the specimen since oil has a higher refractive index (1.56, compared with 1.0 for air and 1.3 for water). To maximize the angle α , and hence $\sin\alpha$, the lenses are also designed to focus very close to the thin coverslip covering the specimen. The term $N \sin\alpha$ is known as the *numerical aperture* (NA) and is usually marked on the objective lens. A good high-magnification lens has an NA of about 1.4 and the very best lenses a value approaching 1.7, and costing as much as a medium-size car! Notice that the magnification is not part of this equation.

Owing to limitations in the values of α , λ , and N based on the physical properties of light, the *limit of resolution* of a light microscope using visible light is about $0.2 \mu\text{m}$ (200 nm). No matter how many times the image is magnified, a conventional light microscope can never resolve objects that are less than $\sim 0.2 \mu\text{m}$ apart or reveal details smaller than $\sim 0.2 \mu\text{m}$ in size. However, some new sophisticated technologies have been devised to ‘beat’ this resolution barrier and can resolve objects just a few nanometers apart; we discuss such a super-resolution microscope in a later section.

Despite this lack of resolution, a conventional microscope can track a single object to within a few nanometers. If we know the precise size and shape of an object—say, a 5-nm sphere of gold that is attached to an antibody in turn bound to a cell-surface protein on a living cell—and if we use a camera to rapidly take multiple digital images, then a computer can calculate the average position to reveal the center of the object to within a few nanometers. In this way, computer algorithms can be used to locate single objects at a more precise level—in this case the location and movement with time of a cell-surface protein labeled with the gold-tagged antibody—than would be possible based on the light microscope’s resolution alone. This technique has been used to measure nanometer-size steps as molecules and vesicles move along cytoskeletal filaments (see Figures 17-29 and 17-30).

Phase-Contrast and Differential-Interference-Contrast Microscopy Visualize Unstained Living Cells

Cells are about 70 percent water, 15 percent protein, 6 percent RNA, and smaller amounts of lipids, DNA, and small molecules. Since none of these major classes of molecules are colored, other methods have to be used to see cells in a microscope. The simplest microscope views cells under *bright-field* optics

(a)

Optical microscope

(b)
Brightfield

Phase-contrast

(d)
Epifluorescence

FIGURE 9-8 Optical microscopes are commonly configured for bright-field (transmitted), phase-contrast, and epifluorescence microscopy. (a) In a typical light microscope, the specimen is usually mounted on a transparent glass slide and positioned on the movable specimen stage. (b) In bright-field light microscopy, light from a tungsten lamp is focused on the specimen by a condenser lens below the stage; the light travels the pathway shown in yellow. (c) In phase-contrast microscopy, incident light passes through an annular diaphragm, which focuses a circular annulus (ring) of light on the sample. Light that passes unobstructed through the specimen is focused by the objective lens onto the thicker gray ring of the phase plate, which absorbs some of the direct light and alters its phase by one-quarter of a wavelength. If a specimen refracts (bends) or diffracts the light, the phase of some light waves is altered (green lines) and the light waves pass through the clear region of the phase plate. The refracted and unrefracted light are recombined at the image plane to form the image. (d) In epifluorescence microscopy, a beam of light from a mercury lamp (gray lines) is directed to the excitation filter that allows just the correct wavelength light to pass (green lines). The light is then reflected off a dichroic filter and through the objective that focuses it on the sample. The fluorescent light emitted by the sample (red lines) passes up through the objective, then through the dichroic mirror and is focused and recorded on the detector at the image plane.

(Figure 9-8b), and little detail can be seen (Figure 9-9). Two common methods for imaging live cells and unstained tissues to generate contrast takes advantage of differences in the refractive index and thickness of cellular materials. These methods, called *phase-contrast microscopy* and *differential-interference-contrast (DIC) microscopy* (or Nomarski interference microscopy), produce images that differ in appearance and reveal different features of cell architecture. Figure 9-9 compares images of live, cultured cells obtained with these two methods and standard bright-field microscopy. Since optical microscopes are expensive, they are often set up to perform many different types of microscopy on the same microscope stand (see Figure 9-8a–d).

Phase-contrast microscopy generates an image in which the degree of darkness or brightness of a region of the sample depends on the *refractive index* of that region. Light moves more slowly in a medium of higher refractive index. Thus a beam of

light is refracted (bent) once as it passes from the medium into a transparent object and again when it departs. In a phase-contrast microscope, a cone of light generated by an annular diaphragm in the condenser illuminates the specimen (see Figure 9-8c). The light passes through the specimen into the objective, and the unobstructed direct light passes through a region of the phase plate that both transmits only a small percentage of the light and changes its phase slightly. The part of a light wave that passes through a specimen will be refracted and will be out of phase (out of synchrony) with the part of the wave that does not pass through the specimen. How much their phases differ depends on the difference in refractive index along the two paths and on the thickness of the specimen. The refracted and unrefracted light are recombined at the image plane to form the image. If the two parts of the light wave are recombined, the resultant light will be brighter if they are in phase and less bright if they are out of phase. Phase-contrast microscopy is suitable for observing single cells or thin cell layers but not thick tissues. It is particularly useful for examining the location and movement of larger organelles in live cells.

DIC microscopy is based on interference between polarized light and is the method of choice for visualizing extremely small details and thick objects. Contrast is generated by differences in the refractive index of the object and its surrounding medium. In DIC images, objects appear to cast a shadow to one side. The “shadow” primarily represents a difference in the refractive index of a specimen rather than its topography. DIC microscopy easily defines the outlines of large organelles, such as the nucleus and vacuole. In addition to having a “relief”-like appearance, a DIC image is a thin *optical section*, or slice, through the object (Figure 9-9, right). Thus details of the nucleus in thick specimens (e.g., an intact *Caenorhabditis elegans* roundworm; see Figure 21-31) can be observed in a series of such optical sections, and the three-dimensional structure of the object can be reconstructed by combining the individual DIC images.

Both phase-contrast and DIC microscopy can be used in *time-lapse microscopy*, in which the same cell is photographed at regular intervals over time to generate a movie.

FIGURE 9-9 Live cells can be visualized by microscopy techniques that generate contrast by interference. These micrographs show live, cultured macrophage cells viewed by bright-field microscopy (left), phase-contrast microscopy (middle), and differential-interference-contrast (DIC) microscopy (right). In a phase-contrast

image, cells are surrounded by alternating dark and light bands; in-focus and out-of-focus details are simultaneously imaged in a phase-contrast microscope. In a DIC image, cells appear in pseudo-relief. Because only a narrow in-focus region is imaged, a DIC image is an optical slice through the object. [Courtesy of N. Watson and J. Evans.]

This procedure allows the observer to study cell movement, provided the microscope's stage can control the temperature of the specimen and the appropriate environment.

Imaging Subcellular Details Often Requires That the Samples Be Fixed, Sectioned, and Stained

Live cells and tissues generally lack compounds that absorb light and so are nearly invisible in a light microscope. Although such specimens can be visualized by the special techniques we just discussed, these methods do not reveal the fine details of structure.

Specimens for light and electron microscopy are commonly fixed with a solution containing chemicals that cross-link most proteins and nucleic acids. Formaldehyde, a common fixative, cross-links amino groups on adjacent molecules; these covalent bonds stabilize protein-protein and protein-nucleic acid interactions and render the molecules insoluble and stable for subsequent procedures. After fixation, a tissue sample for examination by light microscopy is usually embedded in paraffin and cut into sections about 50 μm thick (Figure 9-10a). Cultured cells growing on glass coverslips, as described above, are thin enough so they can be fixed in situ and visualized by light microscopy without the need for sectioning.

A final step in preparing a specimen for light microscopy is to stain it so as to visualize the main structural features of the cell or tissue. Many chemical stains bind to molecules that have specific features. For example, histological samples are often stained with *hematoxylin* and *eosin* ("H&E stain").

Hematoxylin binds to basic amino acids (lysine and arginine) on many different kinds of proteins, whereas eosin binds to acidic molecules (such as DNA and side chains of aspartate and glutamate). Because of their different binding properties, these dyes stain various cell types sufficiently differently that they are distinguishable visually (Figure 9-10b). If an enzyme catalyzes a reaction that produces a colored or otherwise visible precipitate from a colorless precursor, the enzyme can be detected in cell sections by their colored reaction products. Such staining techniques, although once quite common, have been largely replaced by other techniques for visualizing particular proteins, as we discuss next.

Fluorescence Microscopy Can Localize and Quantify Specific Molecules in Live Cells

Perhaps the most versatile and powerful technique for localizing molecules within a cell by light microscopy is **fluorescent staining** of cells and observation by *fluorescence microscopy*. A chemical is said to be fluorescent if it absorbs light at one wavelength (the excitation wavelength) and emits light (fluoresces) at a specific and longer wavelength. Modern microscopes for observing fluorescent samples are configured to pass the excitation light through the objective into the sample and then selectively observe the emitted fluorescent light coming back through the objective from the sample. This is achieved by reflecting the excitation light on a special type of filter called a dichroic mirror into the sample and allowing the light emitted at the longer wavelength to pass through to the observer (see Figure 9-8d).

FIGURE 9-10 Tissues for light microscopy are commonly fixed, embedded in a solid medium, and cut into thin sections. (a) A fixed tissue is dehydrated by soaking in a series of alcohol-water solutions, ending with an organic solvent compatible with the embedding medium. To embed the tissue for sectioning, the tissue is placed in liquid paraffin for light microscopy. After the block containing the

specimen has hardened, it is mounted on the arm of a microtome and slices are cut with a knife. Typical sections cut for light microscopy are 0.5 to 50 μm thick. The sections are collected on microscope slides and stained with an appropriate agent. (b) A section of mouse intestine stained with H&E. [Part (b) © Dr. Gladden Willis/Visuals Unlimited/Corbis.]

EXPERIMENTAL FIGURE 9-11 Fura-2, a Ca^{2+} -sensitive fluorochrome, can be used to monitor the relative concentrations of cytosolic Ca^{2+} in different regions of live cells. (Left) In a moving leukocyte, a Ca^{2+} gradient is established. The highest levels (green) are at the rear of the cell, where cortical contractions take place, and the lowest levels (blue) are at the cell front, where actin undergoes polymerization. (Right) When a pipette filled with chemotactic molecules placed to the side of the cell induces the cell to turn, the Ca^{2+} concentration momentarily increases throughout the cytoplasm and a new gradient is established. The gradient is oriented such that the region of lowest Ca^{2+} (blue) lies in the direction that the cell will turn, whereas a region of high Ca^{2+} (yellow) always forms at the site that will become the rear of the cell. [From R. A. Brundage et al., 1991, *Science* 254:703; courtesy of F. Fay.]

Determination of Intracellular Ca^{2+} and H^{+} Levels with Ion-Sensitive Fluorescent Dyes

The concentration of Ca^{2+} or H^{+} within live cells can be measured with the aid of fluorescent dyes, or *fluorochromes*, whose fluorescence depends on the concentration of these ions. As discussed in later chapters, intracellular Ca^{2+} and H^{+} concentrations have pronounced effects on many cellular processes. For instance, many hormones and other stimuli cause a rise in cytosolic Ca^{2+} from the resting level of about 10^{-7} M to 10^{-6} M, which induces various cellular responses such as the contraction of muscle.

The fluorescent dye *fura-2*, which is sensitive to Ca^{2+} , contains five carboxylate groups that form ester linkages with ethanol. The resulting fura-2 ester is lipophilic and can diffuse from the medium across the plasma membrane into cells. Within the cytosol, esterases hydrolyze fura-2 ester, yielding fura-2, whose free carboxylate groups render the molecule nonlipophilic and thus unable to cross cellular membranes, so it remains in the cytosol. Inside cells, each fura-2 molecule can bind a single Ca^{2+} ion but no other cellular cation. This binding, which is proportional to the cytosolic Ca^{2+} concentration over a certain range, increases the fluorescence of fura-2 at one particular wavelength. At a second wavelength, the fluorescence of fura-2 is the same whether or not Ca^{2+} is bound and provides a measure of the total amount of fura-2 in a region of the cell. By examining cells continuously in the fluorescence microscope and measuring rapid changes in the ratio of fura-2 fluorescence at these two wavelengths, one can quantify rapid changes in the

fraction of fura-2 that has a bound Ca^{2+} ion and thus in the concentration of cytosolic Ca^{2+} (Figure 9-11).

Fluorescent dyes (e.g., SNARF-1) that are sensitive to the H^{+} concentration can similarly be used to monitor the cytosolic pH of living cells. Other useful probes consist of a fluorochrome linked to a weak base that is only partially protonated at neutral pH and that can freely permeate cell membranes. In acidic organelles, however, these probes become protonated; because the protonated probes cannot recross the organelle membrane, they accumulate in the lumen in concentrations manyfold greater than in the cytosol. Thus this type of fluorescent dye can be used to specifically stain mitochondria and lysosomes in living cells (Figure 9-12).

Immunofluorescence Microscopy Can Detect Specific Proteins in Fixed Cells

The common chemical dyes mentioned above stain nucleic acids or broad classes of proteins, but it is much more informative to detect the presence and location of specific proteins. *Immunofluorescence microscopy* is the most widely used method to detect specific proteins with an antibody to which a fluorescent dye has been covalently attached. To do this, you first need to generate antibodies to your specific protein. As discussed briefly in Section 9.1 and in detail in Chapter 23, as part of the response to infection the vertebrate immune

EXPERIMENTAL FIGURE 9-12 Location of lysosomes and mitochondria in a cultured living bovine pulmonary artery endothelial cell. The cell was stained with a green-fluorescing dye that is specifically bound to mitochondria and a red-fluorescing dye that is specifically incorporated into lysosomes. The image was sharpened using a deconvolution computer program discussed later in the chapter. N, nucleus. [Courtesy Invitrogen/Molecular Probes Inc.]

system generates proteins called antibodies that bind specifically to the infectious agent. Cell biologists have made use of this immunological response to generate antibodies to specific proteins. Consider you have purified protein X and then inject it into an experimental animal so that it responds to the protein as a foreign molecule. Over a period of weeks, the animal will mount an immune response and make antibodies to protein X (the “antigen”). If you collect the blood from the animal, it will have antibodies to protein X mixed in with antibodies to many other different antigens, together with all the other blood proteins. You can now covalently bind protein X to a resin and, using affinity chromatography, bind and selectively retain just those antibodies specific to protein X. The antibodies can be eluted from the resin, and now you have a reagent that binds specifically to protein X. This approach generates *polyclonal antibodies* since many different cells in the animal have contributed the antibodies. Alternatively, as we described earlier in this chapter, it is possible to generate a clonal cell line that secretes antibodies to a specific epitope on protein X; these are called *monoclonal antibodies*.

To use either type of antibody to localize the protein, the cells or tissue must first be fixed to ensure that all components remain in place and the cell permeabilized to allow entry of the antibody, commonly done by incubating the cells with a non-ionic detergent or extracting the lipids with an organic solvent. In one version of immunofluorescence microscopy, the antibody is covalently linked to a fluorochrome. Commonly used fluorochromes include rhodamine and Texas red,

which emit red light; Cy3, which emits orange light; and fluorescein, which emits green light. When a fluorochrome-antibody complex is added to a permeabilized cell or tissue section, the complex will bind to the corresponding antigen, then light up when illuminated by the exciting wavelength. Staining a specimen with different dyes that fluoresce at different wavelengths allows multiple proteins as well as DNA to be localized within the same cell (see chapter opening figure).

The most commonly used variation of this technique is called *indirect immunofluorescence microscopy* since the specific antibody is detected indirectly. In this technique, an unlabeled monoclonal or polyclonal antibody is applied to the cells or fixed tissue section, followed by a second fluorochrome-tagged antibody that binds to the constant (Fc) segment of the first antibody. For example, a “second” antibody can be generated by immunizing a goat with the Fc segment that is common to all rabbit IgG antibodies; when coupled to a fluorochrome, this second antibody preparation (called “goat anti-rabbit”) will detect any rabbit antibody used to stain a tissue or cell (Figure 9-13). Because several goat anti-rabbit antibody molecules can bind to a single rabbit antibody molecule in a section, the fluorescence is generally much brighter than if a directly coupled single fluorochrome antibody is used. This approach is often extended to do *double-label fluorescence microscopy*, in which two proteins can be visualized simultaneously. For example, both proteins can be visualized by indirect immunofluorescence microscopy using first antibodies made in different animals (e.g., rabbit and chicken) and the second antibodies

FIGURE 9-13 A specific protein can be localized in fixed tissue sections by indirect immunofluorescence microscopy. To localize a protein by immunofluorescence microscopy, a tissue section, or sample of cells, has to be chemically fixed and made permeable to antibodies (step 1). The sample is then incubated with a primary antibody that binds specifically to the antigen of interest and then unbound antibody removed by washing (step 2). The sample is next incubated with a fluorochrome-labeled secondary antibody that specifically binds to the primary antibody, and again excess secondary antibody is removed by washing (step 3). The sample is then mounted in specialized mounting

medium and examined in a fluorescence microscope (step 4). In this example, a section of the rat intestinal wall was stained with Evans blue, which generates a nonspecific red fluorescence, and GLUT2, a glucose transport protein, was localized by indirect immunofluorescence microscopy. GLUT2 is seen to be present in the basal and lateral sides of the intestinal cells but is absent from the brush border, composed of closely packed microvilli on the apical surface facing the intestinal lumen. Capillaries run through the lamina propria, a loose connective tissue beneath the epithelial layer. [B. Thorens et al., 1990, *Am. J. Physiol.* 259:C279; courtesy of B. Thorens.]

EXPERIMENTAL FIGURE 9-14 Double-label fluorescence microscopy can visualize the relative distributions of two proteins.

In double-label fluorescence microscopy, each protein has to be labeled specifically with different fluorochromes. The diagram at left shows how this can be done: a cultured cell was fixed and permeabilized and then incubated with Rhodamine-labeled phalloidin, a reagent that specifically binds to filamentous actin. It was also incubated with rabbit antibodies to tubulin, the major component of microtubules, followed by a fluorescein-labeled second goat-anti-rabbit antibody. The upper panels on the right show the fluorescein-stained tubulin (*left*) and Rhodamine-stained actin (*right*) and the lower panel the electronically merged images. [Part (right) Courtesy of A. Bretscher.]

(e.g., goat-anti-rabbit and sheep-anti-chicken) labeled with different fluorochromes. In another variation, one protein can be visualized by indirect immunofluorescence microscopy and the second protein by a dye that specifically binds to it. Once the individual images are taken on the fluorescence microscope, their images can be merged electronically (Figure 9-14).

In another widely used version of this technology, molecular biology techniques are used to make a cDNA encoding a recombinant protein to which is fused a short sequence of amino acids called an *epitope tag*. When expressed in cells, this cDNA will generate the protein linked to the specific tag. Two commonly used epitope tags are called FLAG, encoding the amino acid sequence DYKDDDDK (single-letter code), and myc, encoding the sequence EQKLISEEDL. Commercial fluorochrome-coupled monoclonal antibodies to the FLAG or myc epitopes can then be used to detect the recombinant protein in the cell. In an extension of this technology to allow the simultaneous visualization of two proteins, one protein can be tagged with FLAG and a different protein with myc. Each tagged protein is then visualized with a different color, for example, with a rhodamine-labeled antibody to the myc epitope and a fluorescein-labeled antibody to the FLAG epitope.

Tagging with Fluorescent Proteins Allows the Visualization of Specific Proteins in Living Cells

The jellyfish *Aequorea victoria* expresses a naturally fluorescent protein, called *green fluorescent protein* (GFP, ~27 kD). GFP contains a serine, tyrosine, and glycine sequence whose side chains spontaneously cyclize to form a green-fluorescing

chromophore when illuminated with blue light. Using recombinant DNA technologies, it is possible to make a DNA construct in which the coding sequence of GFP is fused to the coding sequence of a protein of interest. When introduced and expressed in cells, a GFP “tagged” protein is made in which the protein of interest is covalently linked to GFP as part of the same polypeptide. Although GFP is a moderate-size protein, the function of the protein of interest is often not changed by fusing it to GFP. This now allows one to visualize GFP—and hence the protein of interest. Not only can one immediately see the localization of the GFP-tagged protein, but one can view its distribution in a living cell over time and thereby assess its dynamics or track its localization following various cell treatments. The simple idea of tagging specific proteins with GFP has revolutionized cell biology and led to the development of many different fluorescent proteins (Figure 9-15). One use of this colorful variety of fluorescent proteins allows one to visualize two or more proteins simultaneously if they are each tagged with a different-colored fluorescent protein. We describe additional techniques that exploit fluorescent proteins in later sections.

Deconvolution and Confocal Microscopy Enhance Visualization of Three-Dimensional Fluorescent Objects

Conventional fluorescence microscopy has two major limitations. First, the fluorescent light emitted by a sample comes not only from the plane of focus but also from molecules above and below it; thus the observer sees a blurred image

FIGURE 9-15 Many different colors of fluorescent proteins are now available. (a) Tubes show the emission colors and names of many different fluorescent proteins, and (b) an agar dish is illuminated

to show growing bacteria expressing several different-colored fluorescent proteins. [R. Tsien.]

caused by the superposition of fluorescent images from molecules at many depths in the cell. The blurring effect makes it difficult to determine the actual molecular arrangements. Second, to visualize thick specimens, consecutive (serial) images at various depths through the sample must be collected and then aligned to reconstruct structures in the original thick tissue. Two general approaches have been developed to obtain high-resolution three-dimensional information. Both these

methods require the image to be collected electronically so that it can then be computationally manipulated as necessary.

The first approach is called *deconvolution microscopy*, which uses computational methods to remove fluorescence contributed from out-of-focus parts of the sample. Consider a three-dimensional sample in which images from three different focal planes are recorded. Since the whole sample is illuminated, the image from plane 2 will contain out-of-focus

EXPERIMENTAL FIGURE 9-16 Deconvolution fluorescence microscopy yields high-resolution optical sections that can be reconstructed into one three-dimensional image. A macrophage cell was stained with fluorochrome-labeled reagents specific for DNA (blue), microtubules (green), and actin microfilaments (red). The series of fluorescent images obtained at consecutive focal planes (optical sections) through the cell were recombined in three dimensions. (a) In

this three-dimensional reconstruction of the raw images, the DNA, microtubules, and actin appear as diffuse zones in the cell. (b) After application of the deconvolution algorithm to the images, the fibrillar organization of microtubules and the localization of actin to adhesions become readily visible in the reconstruction. [Courtesy of J. Evans, Whitehead Institute.]

fluorescence from planes 1 and 3. If you knew exactly how out-of-focus fluorescence from planes 1 and 3 contributed to light collected in plane 2, you could computationally remove it. To gain this information for a particular microscope, a series of images of focal planes are made from a test slide containing tiny fluorescent beads. Each bead represents a pinpoint of light that becomes a blurred object outside its focal plane; from these images a *point spread function* is determined that enables the investigator to calculate the distribution of fluorescent point sources that contributed to the “blur” when out of focus. Having calibrated the microscope in this manner, the experimental series of images can be computationally deconvolved. Images restored by deconvolution display impressive detail without any blurring, as illustrated in Figure 9-16.

The second approach to obtaining better three-dimensional information is called *confocal microscopy* because it uses optical methods to obtain images from a specific focal plane and exclude light from other planes. By collecting a series of images focused through the vertical depth of the

sample, an accurate three-dimensional representation can be computationally generated. Two types of confocal microscopes are in common use today, a *point-scanning* confocal microscope (also known as a laser-scanning confocal microscope, or LSCM) and a *spinning disk* confocal microscope. The idea behind each microscope is to both illuminate and collect emitted fluorescent light in just one small area of a focal plane at a time in such a way that out-of-focus light is excluded. This can be achieved by collecting the emitted light through a pinhole before reaching the detector—light from the focal plane passes through, whereas light from other focal planes is largely excluded. The illuminated area is then moved across the whole focal plane to build up the image electronically. The two types of microscopes differ in how they cover the image. The point-scanning microscope uses a point laser light source at the excitation wavelength to rapidly scan the focal plane in a raster pattern, with the emitted fluorescence collected by a photomultiplier tube, and thereby build up an image (Figure 9-17a). It can then take a

(a) Laser-Scanning Confocal Microscope

(b) Spinning Disk Confocal Microscope

FIGURE 9-17 Light paths for two types of confocal microscopy.

Both types of microscopy are assembled around a conventional fluorescence microscope (yellow shading). The diagram in (a) depicts the light path in a laser scanning confocal microscope. A single-wavelength point of light from an appropriate laser is reflected off a dichroic mirror and bounces off two scanning mirrors and from there through the objective to illuminate a spot in the specimen. The scanning mirrors rock back and forth in such a way that the light scans the sample in a raster fashion (see green lines in the sample). The fluorescence emitted by the sample passes back through the objective and is bounced off the scanning mirrors onto the dichroic mirror. This allows the light to pass through toward the pinhole. This pinhole excludes light from out-of-focus focal planes, so the light reaching the photomultiplier

tube comes almost exclusively from the illuminated spot in the focal plane. A computer then takes these signals and reconstructs the image. The diagram in (b) depicts the light path in a spinning disk confocal microscope. Here instead of using two scanning mirrors, the beam from the laser is spread to focus on pinholes in a spinning disk. The excitation light passes through the objective to provide point illumination of a number of spots in the sample. The fluorescence emitted passes back through the objective, through the holes in the spinning disk, and is then bounced off a dichroic mirror into a sensitive digital camera. The pinholes in the disk are arranged so that as it spins, it rapidly illuminates all parts of the sample several times. As the disk spins fast, for example at 3,000 rpm, very dynamic events in living cells can be recorded.

(a) Conventional fluorescence microscopy

FIGURE 9-18 Confocal microscopy produces an in-focus optical section through thick cells. A mitotic fertilized egg from a sea urchin (*Psammechinus*) was lysed with a detergent, exposed to an anti-tubulin antibody, and then exposed to a fluorescein-tagged antibody that binds to the anti-tubulin antibody. (a) When viewed by conventional fluorescence microscopy, the mitotic spindle is blurred. This blurring

(b) Confocal fluorescence microscopy

occurs because background fluorescence is detected from tubulin above and below the focal plane as depicted in the sketch. (b) The confocal microscopic image is sharp, particularly in the center of the mitotic spindle. In this case, fluorescence is detected only from molecules in the focal plane, generating a very thin optical section. [Micrographs from J. G. White et al., 1987, *J. Cell Biol.* **104**:41.]

series of images at different depths in the sample to generate a three-dimensional reconstruction. A point-scanning confocal microscope can provide exceptionally high-resolution images in both two and three dimensions (Figure 9-18), although it has two minor limitations. First, it can take significant time to scan each focal plane, so if a very dynamic process is being imaged, the microscope may not be able to collect images fast enough to follow the dynamics. Second, it illuminates each spot with intense laser light that can bleach the fluorochrome being imaged and therefore limit the number of images that can be collected.

The spinning disk microscope circumvents these two problems (see Figure 9-17b). The excitation light from a laser is spread out and illuminates a small part of the disk spinning at high speed, for example at 3000 rpm. The disk in fact consists of two linked disks: one with 20,000 lenses that precisely

focuses the laser light on 20,000 pinholes of the second disk. The pinholes are arranged in such a way that they completely scan the focal plane of the sample several times with each turn of the disk. The emitted fluorescent light returns through the pinholes of the second disk and is reflected by a dichroic mirror and focused onto a highly sensitive digital camera. In this way, the sample is scanned in less than a millisecond, and so the real-time location of a fluorescent reporter can be captured even if it is highly dynamic (Figure 9-19). A current limitation of a spinning disk microscope is that the pinhole size is fixed and has to be matched to the magnification of the objective, so it is generally configured for use with a 63× or 100× objective and is less useful for the lower-magnification imaging that might be required in tissue sections. Thus the point-scanning and spinning disk confocal microscopes have overlapping and complementary strengths.

VIDEO: Microtubule Dynamics in Fission Yeast

EXPERIMENTAL FIGURE 9-19 The dynamics of microtubules can be imaged on the spinning disk confocal microscope.

Six frames from a movie of GFP-tubulin in two of the rod-shaped cells of fission yeast are shown. [Courtesy of Fred Chang.]

EXPERIMENTAL FIGURE 9-20 Fluorescent samples in a restricted focal plane can be imaged by total internal reflection (TIRF) microscopy. (a) In TIRF microscopy only about 50 to 100 nm adjacent to the coverslip is illuminated so that fluorescent molecules in the rest of the sample are not excited. This limited illumination is achieved by directing the illuminating light at an angle where it is reflected from the glass-water interface of the coverslip rather than passing through it. Whereas most of the light is reflected, it also generates a very small region of illumination called the evanescent wave (depicted in light blue). (b) Immunofluorescence microscopy with tubulin antibody has been used to visualize microtubules viewed by conventional fluorescence microscopy (top panel), TIRF (middle panel), and a merged image. The two images were collected and false colored red and green so that the merge could highlight those microtubules that are close to the coverslip (green). [Part (b) from J. B. Manneville et al., 2010, *J. Cell Biol.* **191**:585.]

TIRF Microscopy Provides Exceptional Imaging in One Focal Plane

The confocal microscopes we have just described provide amazing and informative images. However, they are not perfect, and some experimental situations call for fluorescence imaging in a thin focal plane adjacent to a surface. For example, confocal imaging is not ideal for exploring the details of proteins at adhesion sites between a cell and a coverslip or to follow the kinetics of assembly of microtubules attached to a coverslip. Both these situations can be imaged at high sensitivity using *total internal reflection fluorescence* (TIRF) microscopy. In the most common configuration of TIRF microscopy, the excitation beam of light comes through the objective lens (Figure 9-20a). However, the angle at which the light arrives at the coverslip is adjusted to the critical angle so that the light is reflected off the coverslip and returns up through the objective. This generates a narrow band, called an *evanescent wave*, that illuminates only about 50 to 100 nm of the sample adjacent to the coverslip, with no illumination to the rest of the sample. Thus if you have a complex mixture of fluorescent structures in a specimen, in the TIRF microscope you will see only those that are within 50 to 100 nm (2 to 4 times the thickness of a microtubule) of the coverslip. When cells are grown on a coverslip,

TIRF has been exceptionally useful in identifying structures on the bottom of cells and therefore close to the coverslip (Figure 9-20b) and for measuring the kinetics of assembly and disassembly of structures such as microtubules and actin filaments (see Chapters 17 and 18).

FRAP Reveals the Dynamics of Cellular Components

Live cell fluorescence imaging reveals the location and bulk dynamics of populations of fluorescent molecules, but it doesn't tell you how dynamic individual molecules are. For example, if we see that a GFP-labeled protein forms a patch at the surface of a cell, does this represent a stable collection of fluorescent protein molecules or a dynamic equilibrium with fluorescent proteins coming in and out of the patch? We can investigate this question by observing the dynamics of the molecules in the patch (Figure 9-21). If we use a high-intensity light to permanently bleach the fluorochrome (e.g., GFP) just in the patch, there will initially be no fluorescence coming

EXPERIMENTAL FIGURE 9-21 Fluorescence recovery after photobleaching (FRAP) reveals the dynamics of molecules. In a living cell, following the distribution of a GFP-labeled protein provides a view of the overall distribution of the protein, but it doesn't tell you how dynamic populations of individual molecules might be. This can be determined by FRAP. (a) In this technique, the GFP signal is bleached by a short burst of strong laser light focused on the region of interest (ROI). This rapidly bleaches the molecules irreversibly, so they are not detected again. Restoration of fluorescence into the region

from it and it will look dark in the fluorescence microscope. However, if the components in the patch are in dynamic equilibrium with unbleached molecules elsewhere in the cell, the bleached molecules will be replaced by unbleached ones, and the fluorescence will begin to come back. The rate of fluorescence recovery is a measure of the dynamics of the molecules. This technique, known as *fluorescence recovery after photobleaching (FRAP)*, has revealed how very dynamic many components in cells are. For example, it has been used to determine the diffusion coefficient of membrane proteins

represents unbleached molecules that have moved into the ROI.

(b) The mobility of GFP-serotonin receptors on the cell surface observed using FRAP. The fluorescence in two regions is followed—one that is bleached (region 1) and a control region that is not (region 2). (c) By quantitating the recovery, the dynamic properties of the serotonin receptor can be established. [Part (b) from S. Kalipatnapu, 2007, *Membrane Organization and Dynamics of the Serotonin 1A Receptor Monitored using Fluorescence Microscopic Approaches*, in *Serotonin Receptors in Neurobiology*, A. Chattopadhyay, ed. CRC press.]

(see Figure 10-10), the dynamics of specific components of the secretory pathway.

FRET Measures Distance Between Chromophores

Fluorescence microscopy can also be used to determine if two proteins interact *in vivo* using a technique called *Förster resonance energy transfer (FRET)*. This technique utilizes two fluorescent proteins in which the emission wavelength of the first is the same as the excitation wavelength of the second (Figure

9-22). For example, when cyan fluorescent protein (CFP) is excited with 440-nm wavelength light, it fluoresces and emits light at 480 nm. If yellow fluorescent protein (YFP) is close by, it will absorb the 480-nm light and emit light at 535 nm. The efficiency of energy transfer is proportional to R^6 , where R is the distance between the fluorophores—it is therefore very

FIGURE 9-22 Protein-protein interactions can be visualized by FRET. The idea behind FRET is to use two different fluorescent proteins so that when one is excited, its emission will excite the second fluorescent protein provided they are sufficiently close (upper panel). In this example, cyan fluorescent protein (CFP) is fused to protein X, yellow fluorescent protein (YFP) is fused to protein Y, and both proteins are expressed in a living cell. If the cell is now illuminated with 440-nm light, the CFP will emit a fluorescent signal at 480 nm. If YFP is not close by, it will not absorb the 480-nm light and no 535-nm light will be emitted. However, if protein X interacts with protein Y (as shown), it will bring CFP close to YFP, the emitted 480-nm light will be captured by YFP, and it will emit light at 535 nm. (b) In this mouse fibroblast, FRET has been used to reveal that the interaction between an active regulatory protein (Rac) and its binding partner is localized to the front of a migrating cell. [Part (b) from R. B. Sekar and Periasamy, 2003, *J. Cell Biol.* 160:629.]

sensitive to small changes in distance and in practice is not detectable at >10 nm. Thus by illuminating an appropriate sample with 440-nm light and observing at 535 nm, one can tell if proteins separately tagged with CFP and YFP are in very close proximity. For example, FRET sensors have been developed to determine where in a cell signaling between a small GTP-binding protein and its effector occurs (Figure 9-22b).

A modified version of this technique can be used to measure conformational changes in a protein. For example, a sensor called *cameleon* has been designed to measure intracellular levels of Ca^{2+} . *Cameleon* consists of a single polypeptide containing both CFP and YFP joined by a piece of polypeptide capable of binding Ca^{2+} (Figure 9-23a). In the absence of Ca^{2+} , the CFP

EXPERIMENTAL FIGURE 9-23 FRET biosensors can detect local biochemical environments. (a) A FRET biosensor is a fusion protein containing two fluorescent proteins linked by a region sensitive to the environment under study. In this example, a protein construct called *cameleon* consists of CFP linked to YFP by a sequence based on the protein calmodulin that undergoes a large conformational change when it binds Ca^{2+} . In the absence of Ca^{2+} , the two fluorescent proteins are too far apart to undergo FRET, whereas when the local Ca^{2+} rises, they are brought sufficiently close to undergo FRET. (b) An example of the use of *cameleon* reveals the oscillation in local Ca^{2+} levels in an *Arabidopsis* growing root tip. [Part (b) from G. B. Monshausen et al., 2008, *Plant Physiol.* 147:1690–1698.]

and YFP are not close enough for FRET to occur. However, in the presence of an appropriate local concentration of Ca^{2+} , cameleon binds Ca^{2+} and undergoes a conformational change that brings CFP and YFP in close proximity, and they can now undergo FRET. Sensors such as cameleon can be used to measure the level of Ca^{2+} in living cells, for example in a growing root tip (Figure 9-23b). Creative researchers are developing FRET sensors to illuminate many different types of local environments; for example, it is possible to make a probe that undergoes FRET only when it becomes phosphorylated by a specific kinase and thereby reveal where in the cell the active kinase is localized.

Super-Resolution Microscopy Can Localize Proteins to Nanometer Accuracy

As we discussed earlier, the theoretical resolution limit of the fluorescence microscope is about $0.2\ \mu\text{m}$ ($200\ \text{nm}$). To understand why this is, consider two fluorescent structures separated by $100\ \text{nm}$. When you try to image them, they each generate a Gaussian distribution of fluorescence, which

overlap so much that they look like one structure. New methods have been developed to get around this problem, one of which is called *photo-activated localization microscopy* (PALM). It relies on the ability of a variant of GFP to be photoactivated; that is, it only becomes fluorescent when activated by a specific wavelength of light, different from its excitation wavelength. Consider what would happen if you could activate just one GFP molecule. When you excite the sample, the one activated GFP would emit many hundreds of photons, giving rise to a Gaussian distribution (Figure 9-24a). Although analysis of each photon does not tell you precisely where the GFP is, the center of the peak can tell you where the GFP is located with nanometer accuracy. If you now activate another GFP, you can localize it individually with the same precision. In PALM, a small percentage of GFPs are activated and each localized with high precision, and then another set is activated and localized, and as additional cycles of activation and localization are recorded, a high-resolution image emerges. For example, the three-dimensional distribution of microtubules can be seen with much greater clarity than with any other light-microscopic method (Figure 9-24b) and a clathrin-coated pit—about $100\ \text{nm}$ in diameter—

EXPERIMENTAL FIGURE 9-24 Super-resolution microscopy can generate light-microscope images with nanometer resolution. The theoretical resolution of the light microscope can be circumvented by super-resolution microscopy, where single molecules are imaged individually/separately to generate a composite image. One version of this technology images proteins fused to photo-activatable GFP in fixed samples. (a) When a GFP is activated and then excited, it will emit thousands of photons that can be collected. This generates a Gaussian curve centered around the location of the emitting GFP; the center provides the location of the GFP to nanometer accuracy. This process is reiterated hundreds of times to excite other GFP molecules, and a high-resolution image emerges. (b) A confocal image of microtubules (*left*) is compared with a corresponding super-resolution image (*right*) in which the three-dimensional arrangement of the microtubules is color coded. (c) The circular nature of a clathrin-coated pit (discussed in Chapter 14) is shown—a confocal image of this structure would look like two bright spots without any detail visible. [Parts (b) and (c) from B. Huang et al., 2008, *Science* **319**:810–813.]

can be seen in remarkable detail (Figure 9-24c). These types of images can take up to an hour to generate, so they are restricted to fixed images and currently cannot be used for imaging proteins in live cells.

KEY CONCEPTS of Section 9.2

Light Microscopy: Exploring Cell Structure and Visualizing Proteins Within Cells

- The resolution of the light microscope, about 0.2 μm , is limited by the wavelength of light.
- Because most cellular components are not colored, differences in refractive index can be used to observe parts of single cells employing phase-contrast and interference-contrast microscopy.
- Tissues generally have to be fixed, sectioned, and stained for cells and subcellular structures to be observed.
- Fluorescence microscopy makes use of compounds that absorb light at one wavelength and emit it at a longer wavelength.
- Ion-sensitive fluorescent dyes can measure intracellular concentrations of ions, such as Ca^{2+} .
- Immunofluorescence microscopy makes use of antibodies to localize specific components in fixed and permeabilized cells.
- Indirect immunofluorescence microscopy uses an unlabeled primary antibody, followed by a fluorescently labeled secondary antibody, that recognizes the primary one and allows it to be localized.
- Short sequences encoding epitope tags can be appended to protein-encoding sequences to allow localization of the expressed protein using an antibody to the epitope tag.
- Green fluorescence protein (GFP) and its derivatives are naturally occurring fluorescent proteins.
- Fusing GFP to a protein of interest allows its localization and dynamics to be explored in a living cell.
- Deconvolution and confocal microscopy provide greatly improved clarity in fluorescent images by removing out-of-focus fluorescent light.
- Total internal reflection (TIRF) microscopy allows fluorescent samples adjacent to a coverslip to be seen with great clarity.
- Fluorescence recovery after photobleaching (FRAP) of a GFP fusion protein allows the dynamics of the population of molecules to be analyzed.
- Förster resonance energy transfer (FRET) is a technique in which light energy is transferred from one fluorescent protein to another when the proteins are very close, thereby revealing when two molecules are close in the cell.
- Super-resolution microscopy allows for detailed fluorescent images at nanometer resolution.

9.3 Electron Microscopy: High-Resolution Imaging

Electron microscopy of biological samples, such as single proteins, organelles, cells, and tissues, offers a much higher resolution of ultrastructure than can be obtained by light microscopy. The short wavelength of electrons means that the limit of resolution for a transmission electron microscope is theoretically 0.005 nm (less than the diameter of a single atom), or 40,000 times better than the resolution of a light microscope and 2 million times better than that of the unaided human eye. However, the effective resolution of the transmission electron microscope in the study of biological systems is considerably less than this ideal. Under optimal conditions, a resolution of 0.10 nm can be obtained with transmission electron microscopes, about 2000 times better than with conventional high-resolution light microscopes.

The fundamental principles of electron microscopy are similar to those of light microscopy; the major difference is that electromagnetic lenses focus a high-velocity electron beam instead of the visible light used by optical lenses. In the *transmission electron microscope (TEM)*, electrons are emitted from a filament and accelerated in an electric field. A condenser lens focuses the electron beam onto the sample; objective and projector lenses focus the electrons that pass through the specimen and project them onto a viewing screen or other detector (Figure 9-25, *left*). Because atoms in air absorb electrons, the entire tube between the electron source and the detector is maintained under an ultrahigh vacuum. Thus living material cannot be imaged by electron microscopy.

In this section, we describe various different approaches to viewing biological material by electron microscopy. The most widely used instrument is the transmission electron microscope, but also in common usage is the *scanning electron microscope (SEM)*, which provides complementary information as we discuss at the end of this section.

Single Molecules or Structures Can Be Imaged After a Negative Stain or Metal Shadowing

It is common in biology to explore the detailed shape of single macromolecules, such as proteins or nucleic acids, or of structures, such as viruses and the filaments that make up the cytoskeleton. It is relatively easy to view these in the transmission electron microscope provided they are stained with a heavy metal that scatters the incident electrons. To prepare a sample, it is first absorbed to a 3-mm *electron microscope grid* (Figure 9-26a) coated with a thin film of plastic and carbon. The sample is then bathed in a solution of a heavy metal, such as uranyl acetate, and excess solution removed (Figure 9-26b). As a result of this procedure, the uranyl acetate coats the grid but is excluded from the regions where the sample has adhered. When viewed in the TEM, you observe where the stain has been excluded, and so the sample is said to be *negatively stained*. Because the stain can precisely reveal the

FIGURE 9-25 In electron microscopy, images are formed from electrons that pass through a specimen or are scattered from a metal-coated specimen. In a transmission electron microscope (TEM), electrons are extracted from a heated filament, accelerated by an electric field, and focused on the specimen by a magnetic condenser lens. Electrons that pass through the specimen are focused by a series of magnetic objective and projector lenses to form a magnified image of the specimen on a detector, which may be a fluorescent viewing screen, a photographic film, or a charged-couple device (CCD) camera. In a scanning electron microscope (SEM), electrons are focused by condenser and objective lenses on a metal-coated specimen. Scanning coils move the beam across the specimen, and electrons scattered from the metal are collected by a photomultiplier tube detector. In both types of microscopes, because electrons are easily scattered by air molecules, the entire column is maintained at a very high vacuum.

topology of the sample, a high-resolution image can be obtained (Figure 9-26c).

Samples can also be prepared by *metal shadowing*. In this technique, the sample is absorbed to a small piece of mica, then coated with a thin film of platinum by evaporation of the metal, followed by dissolving the sample with acid or bleach. The platinum coating can be generated from a fixed angle or at a low angle as the sample is rotated, in which case it is called *low-angle rotary shadowing*. When the sample is transferred to a grid and examined in the TEM, these tech-

FIGURE 9-26 Transmission electron microscopy of negatively stained samples reveals fine features. (a) Samples for transmission electron microscopy (TEM) are usually mounted on a small copper or gold grid. The grid is usually covered with a very thin film of plastic and carbon to which a sample can adhere. (b) The specimen is then incubated in a heavy metal, such as uranyl acetate, and excess stain removed. (c) When observed in the TEM, the sample excludes the stain, so it is seen in negative outline. The example in (c) is a negative stain of rotaviruses. [Part (c) ISM/Phototake.]

niques provide information about the three-dimensional topology of the sample (Figure 9-27).

Cells and Tissues Are Cut into Thin Sections for Viewing by Electron Microscopy

Single cells and pieces of tissue are too thick to be viewed directly in the standard transmission electron microscope. To overcome this, methods were developed to prepare and cut *thin sections* of cells and tissues. When these were examined

FIGURE 9-27 Metal shadowing makes surface details on very small objects visible by transmission electron microscopy. (a) The sample is spread on a mica surface and then dried in a vacuum evaporator (step **1**). The sample grid is coated with a thin film of a heavy metal, such as platinum or gold, evaporated from an electrically heated metal filament (step **2**). To stabilize the replica, the specimen is then coated with a carbon film evaporated from an overhead electrode (step **3**). The biological material is then dissolved by acid and bleach (step **4**), and the remaining metal replica is viewed in a TEM. In

electron micrographs of such preparations, the carbon-coated areas appear light—the reverse of micrographs of simple metal-stained preparations, in which the areas of heaviest metal staining appear the darkest. (b) A platinum-shadowed replica of the substructural fibers of calfskin collagen, the major structural protein of tendons, bone, and similar tissues. The fibers are about 200 nm thick; a characteristic 64-nm repeated pattern (white parallel lines) is visible along the length of each fiber. [Courtesy R. Kessel and R. Kardon.]

in the electron microscope, the organization, beauty, and complexity of the cell interior was revealed and led to a revolution in cell biology—for the first time, new organelles and the first glimpses of the cytoskeleton were seen.

To prepare thin sections, it is necessary to chemically fix the sample, dehydrate it, impregnate it with a liquid plastic that hardens (similar to Plexiglas), and then cut sections of about 5 to 100 nm in thickness. For structures to be seen, the sample has to be stained with heavy metals such as uranium and lead salts, which can be done either before embedding in the plastic or after sections are cut. Examples of cells and tissues viewed by thin-section electron microscopy appear throughout this book (see, for example, Figure 9-33). It is important to realize that the images obtained represent just a thin slice through a cell, so to get a three-dimensional view, it is necessary to cut *serial sections* through the sample and reconstruct the sample from a series of sequential images (Figure 9-28).

Immunoelectron Microscopy Localizes Proteins at the Ultrastructural Level

Just like immunofluorescence microscopy for localizing proteins at the light-microscope level, methods have been

developed to use antibodies to localize proteins in thin sections at the electron microscope level. However, the harsh procedures used to prepare traditional thin sections—chemical fixation and embedding in plastic—can denature or modify the antigens so that they are no longer recognized by the specific antibodies. Gentler methods, such as a light fixation, sectioning material after freezing at the temperature of liquid nitrogen, followed by antibody incubations at room temperature, have been developed. To make the antibody visible in the electron microscope, it has to be attached to an electron-dense marker. One way to do this is to use electron-dense gold particles coated with protein A, a bacterial protein that binds the Fc segment of all antibody molecules (Figure 9-29). Because the gold particles diffract incident electrons, they appear as dark spots.

Cryoelectron Microscopy Allows Visualization of Specimens Without Fixation or Staining

Standard transmission electron microscopy cannot be used to study live cells, and the absence of water causes macromolecules to become denatured and nonfunctional. However,

VIDEO: Three-Dimensional Model of a Golgi Complex

FIGURE 9-28 Model of the Golgi complex based on three-dimensional reconstruction of electron microscopy images.

Transport vesicles (white spheres) that have budded off the rough ER fuse with the *cis* membranes (light blue) of the Golgi complex. By mechanisms described in Chapter 14, proteins move from the *cis* region to the *medial* region and finally to the *trans* region of the Golgi complex. Eventually, vesicles bud off the *trans*-Golgi membranes (orange and red); some move to the cell surface and others move to lysosomes. The Golgi complex, like the rough endoplasmic reticulum, is especially prominent in secretory cells. [Brad J. Marsh & Katheryn E. Howell, *Nature Reviews Molecular Cell Biology* 3, 789-785 (2002).]

hydrated, unfixed, and unstained biological specimens can be viewed directly in a transmission electron microscope if the sample is frozen. In this technique of *cryoelectron microscopy*, an aqueous suspension of a sample is applied to a grid in an extremely thin film, frozen in liquid nitrogen, and maintained in this state by means of a special mount. The frozen sample then is placed in the electron microscope. The very low temperature (-196°C) keeps water from evaporating, even in a vacuum. Thus the sample can be observed in detail in its native, hydrated state without fixing or heavy metal staining. By computer-based averaging of hundreds of images, a three-dimensional model can be generated almost to atomic resolution. For example, this method has been used to generate models of ribosomes, the muscle calcium pump discussed in Chapter 11, and other large proteins that are difficult to crystallize.

Many viruses have coats, or capsids, that contain multiple copies of one or a few proteins arranged in a symmetric array. In a cryoelectron microscope, images of these particles can be viewed from a number of angles. A computer analysis

of multiple images can make use of the symmetry of the particle to calculate the three-dimensional structure of the capsid to about 5-nm resolution. Examples of such images are shown in Figure 4-44.

An extension of this technique, *cryoelectron tomography*, allows researchers to determine the three-dimensional

FIGURE 9-29 Gold particles coated with protein A are used to detect an antibody-bound protein by transmission electron microscopy.

(a) First, antibodies are allowed to interact with their specific antigen (e.g., catalase) in a section of fixed tissue. Then the section is treated with electron-dense gold particles coated with protein A from the bacterium *S. aureus*. Binding of the bound protein A to the Fc domains of the antibody molecules makes the location of the target protein, catalase in this case, visible in the electron microscope. (b) A slice of liver tissue was fixed with glutaraldehyde, sectioned, and then treated as described in part (a) to localize catalase. The gold particles (black dots) indicating the presence of catalase are located exclusively in peroxisomes. [From H. J. Geuze et al., 1981, *J. Cell Biol.* 89:653. Reproduced from the *Journal of Cell Biology* by copyright permission of The Rockefeller University Press.]

FIGURE 9-30 Structure of the nuclear pore complex (NPC) by cryoelectron tomography. (a) In electron tomography, a semicircular series of two-dimensional projection images is recorded from the three-dimensional specimen that is located at the center; the specimen is tilted while the electron optics and detector remain stationary. The three-dimensional structure is computed from the individual two-dimensional images that are obtained when the object is imaged by electrons coming from different directions (arrows in left panel). These individual images are used to generate a three-dimensional image of the object (arrows, right panel). (b) Isolated nuclei from the cellular slime mold *Dictyostelium discoideum* were quick-frozen in liquid

nitrogen and maintained in this state as the sample was observed in the electron microscope. The panel shows three sequential tilted images. Different orientations of NPCs (arrows) are shown in top view (left and center) and side view (right). Ribosomes connected to the outer nuclear membrane are visible, as is a patch of rough ER (arrowheads). (c) Computer-generated surface-rendered representation of a segment of the nuclear envelope membrane (yellow) studded with NPCs (blue). (d) By averaging the images of multiple nuclear pores, much more detail can be discerned. [Part (a) after S. Nickell et al., 2006, *Nature Rev. Mol. Cell. Biol.* **7**:225. Parts (b), (c), and (d) from M. Beck et al., 2004, *Science* **306**:1387.]

architecture of organelles or even whole cells embedded in ice, that is, in a state close to life. In this technique, the specimen holder is tilted in small increments around the axis perpendicular to the electron beam; thus images of the object viewed from different directions are obtained (Figure 9-30a, b). The images are then merged computationally into a three-dimensional reconstruction termed a *tomogram* (Figure 9-30c, d). A disadvantage of cryoelectron tomography is that the samples must be relatively thin, about 200 nm; this is much thinner than the samples (200 μm thick) that can be studied by confocal light microscopy.

Scanning Electron Microscopy of Metal-Coated Specimens Reveals Surface Features

Scanning electron microscopy (SEM) allows investigators to view the surfaces of unsectioned metal-coated specimens. An intense electron beam inside the microscope scans rapidly over the sample. Molecules in the coating are excited and release secondary electrons that are focused onto a scintillation detector; the resulting signal is displayed on a cathode-ray tube much like a conventional television (see Figure 9-25,

FIGURE 9-31 Scanning electron microscopy (SEM) produces a three-dimensional image of the surface of an unsectioned specimen. Shown here is an SEM image of the epithelium lining the lumen of the intestine. Abundant fingerlike microvilli extend from the lumen-facing surface of each cell. The basal lamina beneath the epithelium helps support and anchor it to the underlying connective tissue. Compare this image of intestinal cells with that in Figure 9-13, a fluorescence micrograph. [From R. Kessel and R. Kardon, 1979, *Tissues and Organs: A Text-Atlas of Scanning Electron Microscopy*, W. H. Freeman and Company, p. 176.]

right). The resulting scanning electron micrograph has a three-dimensional appearance because the number of secondary electrons produced by any one point on the sample depends on the angle of the electron beam in relation to the surface (Figure 9-31). The resolving power of scanning electron microscopes, which is limited by the thickness of the metal coating, is only about 10 nm, much less than that of transmission instruments.

KEY CONCEPTS of Section 9.3

Electron Microscopy: High-Resolution Imaging

- Electron microscopy provides very high-resolution images because of the short wavelength of the high-energy electrons used to image the sample.
- Simple specimens, such as proteins or viruses, can be negatively stained or shadowed with heavy metals for examination in a transmission electron microscope (TEM).
- Thicker sections generally must be fixed, dehydrated, embedded in plastic, sectioned, and then stained with electron-dense heavy metals before viewing by TEM.
- Specific proteins can be localized by TEM by employing specific antibodies associated with a heavy metal marker, such as small gold particles.
- Cryoelectron microscopy allows examination of hydrated, unfixed, and unstained biological specimens in the TEM by maintaining them at a few degrees above absolute zero.
- Scanning electron microscopy (SEM) of metal-shadowed material reveals the surface features of specimens.

9.4 Isolation and Characterization of Cell Organelles

The examination of cells by light and electron microscopy led to the appreciation that eukaryotic cells contain a common set of organelles. Most organelles are enclosed in a lipid bilayer and perform a specific function. To perform this function, each type of organelle has a recognizable structure and contains a

specific set of proteins to perform the function. Cell biologists use this fact to identify specific organelles. For example, as discussed in Chapter 12, most of the ATP in a cell is made by ATP synthase, which converts ADP to ATP and is localized in mitochondria, and ATP synthase is a good marker for mitochondria. As we will discuss below, the availability of specific markers for organelles has helped in the development of organelle purification.

In this section, we first give a brief overview of the organelles of eukaryotic cells as a prelude to their discussion in much more detail in later chapters. We then discuss methods that are used to open up cells for the purification of organelles. We end with recent advances in proteomics aimed at defining the complete protein inventory of organelles.

Organelles of the Eukaryotic Cell

The major organelles in animal and plant cells are depicted in Figure 9-32, and some are shown in more detail in Figure 9-33.

The *plasma membrane* encloses the cell and is a vitally important barrier since it is the interface a cell has with its environment, separating the outside world from the internal **cytoplasm**. It is made up of about an equal mass of lipids and proteins. Although the physical properties of the plasma membrane are largely determined by its lipid composition, a membrane's complement of proteins is primarily responsible for the membrane's functional properties. As we discuss in Chapter 13, the plasma membrane is a permeability barrier that contains specific **membrane transport proteins** necessary to bring ions and metabolites into the cell. It is also the site of reception of chemical signals from other cells, so it contains **receptors** that sense these signals and transmits the information across the plasma membrane into the cytosol, a topic we discuss in Chapter 15. The plasma membrane defines the shape of a cell, and so it is intimately associated with the cytoskeleton and with other cells and the cellular matrix, interactions we cover in Chapters 17 through 19.

Larger molecules than ions and metabolites can be taken up by *endocytosis*, a process involving the invagination of the plasma membrane, which then pinches off to form an

Animal cell

Plant cell

FIGURE 9-32 Schematic overview of a “typical” animal cell (top) and plant cell (bottom) and their major substructures. Not every cell will contain all the organelles, granules, and fibrous structures shown

endosome in the cytoplasm. During the best-studied form of endocytosis, special regions of the plasma membrane called *coated pits* are formed in which receptors collect and bring specific molecules or particles into the cell (Figure 9-33a). This process is known as *receptor-mediated endocytosis*. Once materials are internalized, they are sorted and can either be returned to the plasma membrane or delivered to *lysosomes* for degradation. Lysosomes contain a battery of degradative enzymes that can break down essentially any biological molecule into smaller components. The lumen of lysosomes has an acidic pH of 4.5; this helps to denature proteins and the degradative enzymes—collectively known as *acid hydrolases*—can withstand this environment and in fact work optimally at this pH.

The largest internal membrane system is an organelle known as the **endoplasmic reticulum (ER)**, consisting of an extensive

- 1 Plasma membrane controls movement of molecules in and out of the cell and functions in cell-cell signaling and cell adhesion.
- 2 Mitochondria, which are surrounded by a double membrane, generate ATP by oxidation of glucose and fatty acids.
- 3 Lysosomes, which have an acidic lumen, degrade material internalized by the cell and worn-out cellular membranes and organelles.
- 4 Nuclear envelope, a double membrane, encloses the contents of the nucleus; the outer nuclear membrane is continuous with the rough ER.
- 5 Nucleolus is a nuclear subcompartment where most of the cell's rRNA is synthesized.
- 6 Nucleus is filled with chromatin composed of DNA and proteins; site of mRNA and tRNA synthesis.
- 7 Smooth endoplasmic reticulum (ER) synthesizes lipids and detoxifies certain hydrophobic compounds.
- 8 Rough endoplasmic reticulum (ER) functions in the synthesis, processing, and sorting of secreted proteins, lysosomal proteins, and certain membrane proteins.
- 9 Golgi complex processes and sorts secreted proteins, lysosomal proteins, and membrane proteins synthesized on the rough ER.
- 10 Secretory vesicles store secreted proteins and fuse with the plasma membrane to release their contents.
- 11 Peroxisomes detoxify various molecules and also break down fatty acids to produce acetyl groups for biosynthesis.
- 12 Cytoskeletal fibers form networks and bundles that support cellular membranes, help organize organelles, and participate in cell movement.
- 13 Microvilli increase surface area for absorption of nutrients from surrounding medium.
- 14 Cell wall, composed largely of cellulose, helps maintain the cell's shape and provides protection against mechanical stress.
- 15 Vacuole stores water, ions, and nutrients, degrades macromolecules, and functions in cell elongation during growth.
- 16 Chloroplasts, which carry out photosynthesis, are surrounded by a double membrane and contain a network of internal membrane-bound sacs.

here, and other substructures can be present in some. Cells also differ considerably in shape and in the prominence of various organelles and substructures.

interconnected network of flattened membrane-bound sacs and tubules. The ER can be divided into the *smooth endoplasmic reticulum*, so called because the membrane has a smooth surface, and the *rough endoplasmic reticulum*, which is studded with ribosomes (Figure 9-33b). The smooth endoplasmic reticulum is the site of synthesis of fatty acids and phospholipids. In contrast, the rough endoplasmic reticulum with its associated ribosomes is the site of synthesis of membrane proteins and proteins that will be secreted out of a cell, accounting for about one-third of all the different types of proteins synthesized by a cell. After synthesis on the ER, proteins destined for the plasma membrane or for secretion are first transported to the **Golgi complex**, a stack of flattened membranes called *cisternae* (Figure 9-33b), in which the proteins are modified and sorted before being transported to their destination at the plasma membrane

FIGURE 9-33 Examples of organelles viewed by transmission electron microscopy of thin sections. (a) The plasma membrane contains a clathrin-coated pit. Before fixation, the cells were incubated with colloidal gold-labeled transferrin, a protein involved in iron uptake through a receptor localized in coated pits (see Chapter 14). (b) A section through a secretory cell shows the ribosome-studded endoplasmic reticulum and the Golgi complex. (c) The two membranes of a mitochondrion and the membrane infoldings called cristae are shown.

(d) Plants contain chloroplasts, another double-membrane organelle. The thylakoid membranes contain the enzymes of the photosynthetic pathway that involves the conversion of light energy into ATP. [Part (a) from C. Lamaze et al., 1997, *Journal of Biological Chemistry* **272**:20332; part (b) from G. Palade collection; part (c) from D. W. Fawcett, 1981, *The Cell*, 2d ed., Saunders, p. 415; part (d) courtesy of Biophoto Associates/M. C. Ledbetter/ Brookhaven National Laboratory.

or, in some cases, delivered to endosomes. Because proteins destined for secretion are made on the endoplasmic reticulum, transported through the Golgi complex, and released from the cell, this whole process is collectively known as the *secretory pathway*, although it also includes the synthesis and transport of

membrane proteins that will remain in the endoplasmic reticulum, the Golgi complex, and the plasma membrane and are therefore not secreted. These so-called *membrane-trafficking pathways*, encompassing both the endocytic and the secretory pathways, are discussed in detail in Chapter 14.

Another common organelle is the **peroxisome**, a class of roughly spherical organelles that contain *oxidases*—enzymes that use molecular oxygen to oxidize toxins to produce harmless products and for the oxidation of fatty acids for the production of acetyl groups, a topic we come to in Chapter 12.

All the organelles discussed so far are enclosed by a single lipid bilayer membrane. Some organelles, namely the **nucleus**, **mitochondria**, and, in plant cells, **chloroplasts**, have an additional membrane that serves various functions, as we describe below.

The nucleus contains the DNA of the genome and is the site of transcription of the DNA into messenger RNA. The nucleus has an inner membrane that defines the nucleus itself. It also contains an outer membrane that is continuous with the membrane of the endoplasmic reticulum in such a way that the space between the inner and outer nuclear membranes is continuous with the endoplasmic reticulum (see Figure 9-32). Access in and out of the nucleus is provided by tubular connections between the inner and outer membrane stabilized by structures called **nuclear pores**. Nuclear pores not only define the site of transport across the nuclear membranes but act as gatekeepers, only allowing transport of specific macromolecules in and out of the nucleus—an important and fascinating topic we mentioned in Chapter 8 and will discuss in more detail in Chapter 13.

Mitochondria and chloroplasts are believed to have evolved from an event a long time ago when a eukaryotic cell engulfed one type of bacterium that gave rise to mitochondria and a different kind that gave rise to chloroplasts. That mitochondria and chloroplasts have two membranes is evidence supporting this hypothesis. The inner membrane is most likely derived from the original bacterial membrane, whereas the outer membrane is a vestige of the plasma membrane from the engulfment event. There is a lot of evidence for the bacterial origin of these organelles, including the fact that mitochondria and chloroplasts both have their own DNA genome and the biosynthesis of proteins in these organelles is more similar to bacterial protein synthesis than eukaryotic protein synthesis.

Mitochondria can occupy as much as 25 percent of the volume of the cytoplasm. They are thread-like organelles in which the outer membrane contains porin proteins that render the membrane permeable to molecules up to a molecular weight of 10,000. The inner mitochondrial membrane is highly convoluted with infoldings called *cristae* that protrude into the central space, called the *matrix* (Figure 9-33c). A major function of mitochondria is to complete the terminal stages of degradation of glucose by oxidation to generate most of the ATP supply of the cell. Thus mitochondria can be regarded as the “power plants” of the cell.

All plants and green algae are characterized by the presence of chloroplasts (Figure 9-33d), organelles that use *photosynthesis* to capture the energy of light with colored pigments, including the green pigment *chlorophyll*, and ultimately store the captured energy in the form of ATP. The processes by which ATP is made in mitochondria and chloroplasts is described in Chapter 12.

Disruption of Cells Releases Their Organelles and Other Contents

The initial step in purifying subcellular structures is to release the cell's contents by rupturing the plasma membrane and the cell wall, if present. First, the cells are suspended in a solution of appropriate pH and salt content, usually isotonic sucrose (0.25 M) or a combination of salts similar in composition to those in the cell's interior. Many cells can then be broken by stirring the cell suspension in a high-speed blender or by exposing it to ultrahigh-frequency sound (*sonication*). Alternatively, plasma membranes can be sheared by special pressurized tissue homogenizers in which the cells are forced through a very narrow space between a plunger and the vessel wall; the pressure of being forced between the wall of the vessel and the plunger ruptures the cell.

Recall that water flows into cells when they are placed in a hypotonic solution, that is, one with a lower concentration of ions and small molecules than found inside the cell. This osmotic flow can be used to cause cells to swell, weakening the plasma membrane and facilitating its rupture. Generally, the cell solution is kept at 0 °C to best preserve enzymes and other constituents after their release from the stabilizing forces of the cell.

Disrupting the cell produces a mix of suspended cellular components, the homogenate, from which the desired organelles can be retrieved. Because rat liver contains an abundance of a single cell type, this tissue has been used in many classic studies of cell organelles. However, the same isolation principles apply to virtually all cells and tissues, and modifications of these cell-fractionation techniques can be used to separate and purify any desired components.

Centrifugation Can Separate Many Types of Organelles

In Chapter 3, we considered the principles of centrifugation and the uses of centrifugation techniques for separating proteins and nucleic acids. Similar approaches are used for separating and purifying the various organelles, which differ in both size and density and thus undergo sedimentation at different rates.

Most cell-fractionation procedures begin with *differential centrifugation* of a filtered cell homogenate at increasingly higher speeds (Figure 9-34). After centrifugation at each speed for an appropriate time, the liquid that remains at the top of the vessel, called the supernatant, is poured off and centrifuged at higher speed. The pelleted fractions obtained by differential centrifugation generally contain a mixture of organelles, although nuclei and viral particles can sometimes be purified completely by this procedure.

An impure organelle fraction obtained by differential centrifugation can be further purified by *equilibrium density-gradient centrifugation*, which separates cellular components according to their density. After the fraction is resuspended, it is layered on top of a solution that contains a gradient of a dense non-ionic substance (e.g., sucrose or glycerol). The tube is centrifuged at a high speed (about 40,000 rpm) for

FIGURE 9-34 Differential centrifugation is a common first step in fractionating a cell homogenate. The homogenate resulting from disrupting cells is usually filtered to remove unbroken cells and then centrifuged at a fairly low speed to selectively pellet the nucleus—the largest organelle. The undeposited material (the supernatant) is next centrifuged at a higher speed to sediment the mitochondria, chloroplasts, lysosomes, and peroxisomes.

Subsequent centrifugation in the ultracentrifuge at 100,000g for 60 minutes results in deposition of the plasma membrane, fragments of the endoplasmic reticulum, and large polyribosomes. The recovery of ribosomal subunits, small polyribosomes, and particles such as complexes of enzymes requires additional centrifugation at still higher speeds. Only the cytosol—the soluble aqueous part of the cytoplasm—remains in the supernatant after centrifugation at 300,000g for 2 hours.

several hours, allowing each particle to migrate to an equilibrium position where the density of the surrounding liquid is equal to the density of the particle (Figure 9-35). The different layers of liquid are then recovered by pumping out the contents of the centrifuge tube through a narrow piece of tubing and collecting fractions.

Because each organelle has unique morphological features, the purity of organelle preparations can be assessed by examination in an electron microscope. Alternatively, organ-

elle-specific marker molecules can be quantified. For example, the protein cytochrome *c* is present only in mitochondria, so the presence of this protein in a fraction of lysosomes would indicate its contamination by mitochondria. Similarly, catalase is present only in peroxisomes; acid phosphatase, only in

FIGURE 9-35 A mixed-organelle fraction can be further separated by equilibrium density-gradient centrifugation. In this example, utilizing rat liver, material in the pellet from centrifugation at 15,000g (see Figure 9-34) is resuspended and layered on a gradient of increasingly dense sucrose solutions in a centrifuge tube. During centrifugation for several hours, each organelle migrates to its appropriate equilibrium density and remains there. To obtain a good separation of lysosomes from mitochondria, the liver is perfused with a solution containing a small amount of detergent before the tissue is disrupted. During this perfusion period, detergent is taken into the cells by endocytosis and transferred to the lysosomes, making them less dense than they would normally be and permitting a “clean” separation of lysosomes from mitochondria.

lysosomes; and ribosomes, only in the rough endoplasmic reticulum or the cytosol.

Organelle-Specific Antibodies Are Useful in Preparing Highly Purified Organelles

Cell fractions remaining after differential and equilibrium density-gradient centrifugation usually contain more than one type of organelle. Monoclonal antibodies for various organelle-specific membrane proteins are a powerful tool for further purifying such fractions. One example is the purification of vesicles whose outer surface is covered with the protein **clathrin**; these coated vesicles are derived from coated pits at the plasma membrane during receptor-mediated endocytosis (see Figure 9-33a), a topic discussed in detail in Chapter 14. An antibody to clathrin, bound to a bacterial carrier, can selectively bind these vesicles in a crude preparation of membranes, and the whole antibody complex can then be isolated by low-speed centrifugation (Figure 9-36). A related technique uses tiny metallic beads coated with specific antibodies. Organelles that bind to the antibodies, and are thus linked to the metallic beads, are recovered from the preparation by adhesion to a small magnet on the side of the test tube.

All cells contain a dozen or more different types of small membrane-limited vesicles of about the same size (50 to 100

nm in diameter) and density, which makes them difficult to separate from one another by centrifugation techniques. Immunological techniques are particularly useful for purifying specific classes of such vesicles. Fat and muscle cells, for instance, contain a particular glucose transporter (GLUT4) that is localized to the membrane of one of these types of vesicle. When insulin is added to the cells, these vesicles fuse with the plasma membrane and increase the number of glucose transporters able to take up glucose from the blood. As we will see in Chapter 15, this process is critical to maintaining the appropriate concentration of sugar in the blood. The GLUT4-containing vesicles can be purified by using an antibody that binds to a segment of the GLUT4 protein that faces the cytosol. Likewise, the various transport vesicles discussed in Chapter 14 are characterized by unique surface proteins that permit their separation with the aid of specific antibodies.

A variation of this technique is employed when no antibody specific for the organelle under study is available. A gene encoding an organelle-specific membrane protein is modified by the addition of a segment encoding an epitope tag; the tag is placed on a segment of the protein that faces the cytosol. Following stable expression of the recombinant protein in the cell under study, an anti-epitope monoclonal antibody (described above) can be used to purify the organelle.

FIGURE 9-36 Small coated vesicles can be purified by binding of antibody specific for a vesicle surface protein and linkage to bacterial cells. In this example, a suspension of membranes from rat liver is incubated with an antibody specific for clathrin, a protein that coats the outer surface of certain cytosolic vesicles. To this mixture is added a suspension of killed *Staphylococcus aureus* bacteria, whose surface membrane contains protein A, which binds to the constant (Fc

region of antibodies. (a) Interaction of protein A with antibodies bound to clathrin-coated vesicles links the vesicles to the bacterial cells. The vesicle-bacteria complexes can then be recovered by low-speed centrifugation. (b) A thin-section electron micrograph reveals clathrin-coated vesicles bound to an *S. aureus* cell. [See E. Merisko et al., 1982, *J. Cell Biol.* **93**:846. Micrograph courtesy of G. Palade.]

Proteomics Reveals the Protein Composition of Organelles

To identify all the proteins in an organelle requires three steps. First, one has to be able to obtain the organelle in high purity. Second, one has to have a way to identify all the sequences of the proteins in the organelle. This identification is generally done by digesting all the proteins with a protease such as trypsin, which cleaves all polypeptides at lysine and arginine residues, and then determining the mass and sequence of all these peptides by mass spectrometry. Third, one has to have a genomic sequence to identify the proteins from which all the peptides came. In this way, the “proteome” of many organelles has been determined. As one example, a recent proteomic study on mitochondria purified from mouse brain, heart, kidney, and liver revealed 591 mitochondrial proteins, including 163 proteins not previously known to be associated with this organelle. Several proteins were found in mitochondria only in specific cell types. Determining the functions associated with these newly identified mitochondrial proteins is a major objective of current research on this organelle.

KEY CONCEPTS of Section 9.4

Isolation and Characterization of Cell Organelles

- Microscopy has revealed a common set of organelles present in eukaryotic cells (see Figure 9-32).
- Disruption of cells by vigorous homogenization, sonication, or other techniques releases their organelles. Swelling of cells in a hypotonic solution weakens the plasma membrane, making it easier to rupture.
- Sequential differential centrifugation of a cell homogenate yields fractions of partly purified organelles that differ in mass and density.
- Equilibrium density-gradient centrifugation, which separates cellular components according to their densities, can further purify cell fractions obtained by differential centrifugation.
- Immunological techniques using antibodies against organelle-specific membrane proteins are particularly useful in purifying organelles and vesicles of similar sizes and densities.
- Proteomic analysis can identify all the protein components in a preparation of a purified organelle.

9.5 Perturbing Specific Cell Functions

What general approaches have scientists used to understand the function of specific proteins in cell biological processes? We have already discussed in Chapter 3 how proteins can be purified and their properties characterized in detail. In many cases, this has led to the *in vitro* biochemical reconstitution of

complicated biochemical processes, such as DNA replication or protein synthesis. These biochemical approaches have been complemented by genetic approaches, and as we have seen in Chapter 5, mutations can be used to identify genes whose products play specific functions. As we will see in Chapters 14 and 19, classic genetic screens in yeast were used to identify proteins that participate in the secretory pathway and the cell cycle, respectively. Genetic approaches in other organisms, such as the nematode worm, the fruit fly, and the mouse, have contributed immensely to uncovering basic aspects of cell biology and development (see Chapter 1).

Over the last few years, additional new and very powerful approaches have been developed to perturb specific components in living cells and thereby shed light on their functions. In this section, we discuss two of these approaches: the use of specific chemicals to perturb cell function and the use of interfering RNA to suppress the expression of specific genes.

Drugs Are Commonly Used in Cell Biology

Naturally occurring drugs have been used for centuries, but how they worked was often not known. For example, extracts of the meadow saffron were used to treat gout, a painful disease resulting from inflammation of joints. Today we know that the extract contains colchicine, a drug that depolymerizes microtubules and interferes with the ability of white blood cells to move to the sites of inflammation (see Chapter 18). Alexander Fleming discovered that certain fungi secrete compounds that kill bacteria (antibiotics), resulting in the discovery of penicillin. Only later was it discovered that penicillin inhibits bacterial cell division by blocking the assembly of the cell walls of certain bacteria.

Many examples like these have resulted in the discovery of a very wide range of drugs available to inhibit specific and essential processes of cells. In most cases, researchers have eventually been able to identify the molecular target of the drug. For example, there are many other antibiotic drugs that affect aspects of prokaryotic protein synthesis. A selection of some of the more commonly used drugs that affect a broad variety of cell biological processes are listed in Table 9-1, grouped according to the process they inhibit.

Chemical Screens Can Identify New Specific Drugs

How does one discover a new drug? One widely used approach makes use of *chemical libraries* consisting of 10,000s to 100,000s of different compounds to search for chemicals that inhibit a specific process. The screening of chemical libraries in conjunction with high-throughput microscopic techniques has now become one of the major routes for new leads in drug discovery. Here we give just one case to illustrate how this type of approach works.

In our example (Figure 9-37a), researchers wanted to identify compounds that inhibit mitosis, the process where duplicated chromosomes are accurately segregated by a

TABLE 9-1 Selected Set of Small Molecules Used in Cell Biological Research

Some of the following molecules have broad specificity, whereas others are highly specific. More information about many of these compounds can be found in the relevant chapters in this text.

DNA replication inhibitors	Aphidicolin (eukaryotic DNA polymerase inhibitor); camptothecin, etoposide (eukaryotic topoisomerase inhibitors)
Transcription inhibitors	α -Amanitin (eukaryotic RNA polymerase II inhibitor); actinomycin D (eukaryotic transcription elongation inhibitor); rifampicin (bacterial RNA polymerase inhibitor); thiolutin (bacterial and yeast RNA polymerase inhibitor)
Protein synthesis inhibitors—block general protein production; toxic after extended exposure	Cycloheximide (translational inhibitor in eukaryotes); geneticin/G418, hygromycin, puromycin (translation inhibitors in bacteria and eukaryotes); chloramphenicol (translation inhibitor in bacteria and mitochondria); tetracycline (translation inhibitor in bacteria)
Protease inhibitors—block protein degradation	MG-132, lactacystin (proteasome inhibitors); E-64, leupeptin (serine and/or cysteine protease inhibitors); phenylmethanesulfonylfluoride (PMSF) (serine proteases inhibitor); tosyl-L-lysine chloromethyl ketone (TLCK) (trypsin-like serine protease inhibitor)
Compounds affecting the cytoskeleton	Phalloidin, jasplakinolide (F-actin stabilizer); latrunculin, cytochalasin (F-actin polymerization inhibitors); taxol (microtubule stabilizer); colchicine, nocodazole, vinblastine, podophylotoxin (microtubule polymerization inhibitors); monastrol (kinesin-5 inhibitor)
Compounds affecting membrane traffic, intracellular movement and the secretory pathway, protein glycosylation	Brefeldin A (secretion inhibitor); leptomycin B (nuclear protein export inhibitor); dynasore (dynamin inhibitor); tunicamycin (N-linked glycosylation inhibitor)
Kinase inhibitors	Genistein, rapamycin, gleevec (tyrosine kinase inhibitors with various specificities); wortmannin, LY294002 (PI3 kinase inhibitors); staurosporine (protein kinase inhibitor); roscovitine (cell cycle CDK1 and CDK2 inhibitors)
Phosphatase inhibitors	Cyclosporine A, FK506, calyculin (protein phosphatase inhibitors with various specificities); okadaic acid (general inhibitor of serine/threonine phosphatases); phenylarsine oxide, sodium orthovanadate (tyrosine phosphatase inhibitors)
Compounds affecting intracellular cAMP levels	Forskolin (adenylate cyclase activator)
Compounds affecting ions (e.g., K^+ Ca^{2+})	A23187 (Ca^{2+} ionophore); valinomycin (K^+ ionophore); BAPTA (divalent cation (e.g., Ca^{2+}) binding/sequestering agent); thapsigargin (endoplasmic reticulum Ca^{2+} ATPase inhibitor); ouabain (Na^+/K^+ ATPase inhibitor)
Some drugs used in medicine	Propranolol (β -adrenergic receptor antagonist), statins (HMG-CoA reductase inhibitors, block cholesterol synthesis)

microtubule-based machine called the mitotic spindle (discussed in Chapter 18). It was known that if spindle assembly is compromised, cells arrest in mitosis. Therefore, the screen first used an automated robotic method to look for compounds that arrest cells in mitosis. The basis for the inhibition of the candidate compounds was then explored to see if they affected assembly of the microtubules. Since inhibition of microtubule assembly was not of interest, the effect of the remaining candidates on the structure of the spindle was determined by immunofluorescence microscopy with antibodies

to tubulin, the major protein of microtubules. Over 16,000 compounds were screened, and a compound was identified that resulted in cells with abnormal spindles—instead of having two asters, they had a single aster, what is called a mono-astral array (Figure 9-37b). This drug, now called *monastrol*, was found to interfere with the assembly of the spindle by inhibiting a microtubule-based motor called kinesin-5 (see Chapter 18 for more details about the mitotic spindle). Derivatives of monastrol are now being tested as anti-tumor agents for the treatment of certain cancers.

FIGURE 9-37 Screening for drugs that affect specific biological processes. In this example, a chemical library of 16,320 different chemicals was subject to a series of screens for inhibitors of mitosis. Since such an inhibitor is expected to arrest cells at the mitotic stage of the cell cycle, the first screen **1** was to see if any of the chemicals enhanced the level of a marker for mitotic cells, and this yielded 139 candidates. Microtubules make up the structure of the mitotic spindle, and the researchers were not interested in new drugs that target microtubules, so in the second screen **2** they tested the 139 compounds for their ability to affect microtubule assembly, and this eliminated 53 candidates. Immunofluorescence microscopy with antibodies to tubulin (the major subunit of microtubules) together with a stain for DNA was then used in the third screen **3** to identify compounds that disrupt the structure of the spindle. (b) Localization of tubulin (green) and DNA (blue) are shown for an untreated mitotic spindle and one treated with one of the recovered compounds, now called monastrol. Monastrol inhibits a microtubule-based motor called kinesin-5, discussed in Chapter 18, necessary to separate the poles of the mitotic spindle. When kinesin-5 is inhibited, the two poles remain associated to give a monopolar spindle. [Part (b) T. U. Mayer et al., *Science* **286**:971–974.]
